For example, when Hindi is used for Christianity, Islam, and Buddhism, it develops Christian, Islamic, and Buddhist registers, respectively. These registers differ from one another primarily in the religious vocabulary, which varies across religions (for further discussion, see Pandharipande, 1992). The major impact of the use of one language for many religions was that these languages developed a set of vocabulary (which was commonly shared by different religions), the meaning of which was contextually determined. For example, the term *Iśvar* 'god' is interpreted differently in different religious systems, as shown in Figure 13.

In addition, the major impact of the use of NSA languages for many religions is seen in their convergence. Each of the major NSA languages developed similar varieties such as Sanskritized (for Hinduism), Arabicized or Persianized (for Islam), and Englishized (for Christianity) forms that share linguistic features (mainly religious themes and vocabulary). For example, note the Sanskritized Hindi (1a) and (1b) and Tamil (2) in the examples below:

Hindi:
Tulsīdās' (15th century C.E.) *Vinay Patrikā* (*pad*: 43). The underlined portion in the examples is in Sanskrit (Omprakash, 1971: 126):

(1a) vedabodhita-karma-dharma-dharaṇī-dhenu-vipra-sevaka-sadhumodakari
Veda-instructed-action-duty-earth cows-Brahmins-servants-saints-joy giver
'He makes the whole world (earth), cows, Brahmins, and servants happy by performing actions, (religious) duties which are instructed by the Vedas.'

The following example illustrates modern religious prayer in Hindi:

(1b) jay jagadīś hare, svāmī jay jagadīś hare
bhaktajano ke sankaṭa pal me dūra kare.
'Victory to you Hari, who is the lord of the world. O Hari, you are the controller, the lord of the world. You instantaneously remove the troubles of your devotees.'

Tamil :
The following example is from Thirugnasambandhan (1992: 119):

(2) muttukkaḷalum iva naṛpavalannaḷāum
kōttukkalanta tamiḻḻ api samskṛtena
ettikkilum bhavatu hāralateva baddhā
puttikku matkṛtir iyam sudṛṣam vibhāṣā.
'May my composition where Tamil and Sanskrit are mixed and strung together like pearls and excellent corals mixed and strung together in a garland be an embellishment for the intellect everywhere.'

It is important to note here that the use of the different languages has had an impact on the religious content as well. As the medium changed, the message did too (Pandharipande, 1992). The use of NSA languages included metaphors, narratives, and religious themes that were not necessarily part of the earlier scriptures in their corresponding classical languages.

Genres of Religious Discourse

The multiple linkage of religious languages has created an intricate network of genres of religious discourse that provides a framework to determine the language choice in a particular type of religious discourse. Over time, new genres were introduced, coexisted, and at times were replaced. Similarly, the languages chosen for those genres also underwent changes. Although it is difficult to provide a comprehensive survey of the entire range of the genres for each religion, a brief sketch will be presented of the genres in the Hindu religious discourse. The ancient genre of Vedic hymns, rituals, and *mantras* were in Sanskrit poetry, while the philosophical as well as theological discourses, teachings, and dialogues of the *Upaniṣads*, and the *Sūtra* literature were in Sanskrit prose. Similarly, the critical scholarly commentatorial expository discourse was also in Sanskrit prose. A large body of *Stotra* (literally, prayers of praise of deities) literature in the post-Vedic period was in a stylized form of poetry. However, after the 7th and 8th centuries C.E., New South Asian and regional languages began to be used for the transcreation of the Sanskrit classics, e.g., *Jnāneśvarī* (13th century C.E., a commentary/transcreation of the *Bhagavadgītā* in Marathi, Villiputtur Āḷvār's Tamil *Mahābhārata* (1400 C.E.), Kampaṇa's Tamil version of the *Rāmāyaṇa*, *īrāmāvatāram* 'The descent of Rāma,' Tulsīdāsa's Awadhi version of the *Rāmāyaṇa*, *Rāmacaritmānas* (16th century C.E.), etc. Moreover, extremely popular and powerful devotional literature in the premedieval and medieval period was primarily composed in poetry in the regional languages, for

example, the *Vacanas* (in Kannada), *Dohe* and *Padas* (in Old Hindi and Rajastani), etc. Additionally, *Kīrtan* and *Bhajan* established some of the new genres of devotional poetry in regional languages.

A Śaivite woman mystic saint Lalleshvari from Kashmir composed her devotional poetry in the Kashmiri language (Kachru, 1981: 15) in the native form of the meter called *Vāk*.

Authority

The authority that authenticates ideologies and thereby the choice of religious languages in South Asia is dynamic. Traditionally, mystics, saints, church, and Muslim mullahs have been perceived as authorities in determining the choice of religious languages for religions. However, their perception of religious language has changed over time. Thus the mystics of the ancient period did not allow the use of NSA languages, while those in the medieval period did. In contemporary South Asia, mystics and saints do use a mixture of many languages! However, it should be noted here that the mixture of languages is more readily allowed in the oral discourse on religion than in the religious rituals and written discourse.

Although the traditional authority of saints and mystics continues to play a role in authenticating the choice of a code as religious in contemporary South Asia, the 'social magic' (Bourdieu, 1991) is the media that constructs, communicates, and promotes religious languages as symbols of religious/social identities. More specifically, the visual (TV) and audio programs on and about religion play a major role in the communication as well as authentication of religious languages as symbols of identities. For example, Sanskrit (in the religious rituals, mostly weddings) expresses the pan-South-Asian Hindu identity, while the use of a regional language in a prayer at home symbolizes regional Hindu identity.

In addition to this process of symbolization, the linguistic structure of the languages used in the programs is authenticated and gradually institutionalized as religious languages. For example, the languages used by the saints in the religious discourse on television or in the movies on the religious epics are accepted as authentic languages of religion. The most interesting case is that of the TV series on the Hindu epics, the *Rāmāyaṇa* and the *Mahābhārata*. The language of the epics in these series is Hindi mixed with Sanskrit. However, the genre is new. The vocabulary, syntax, and the symbols depict a novel composite of a genre that is intentionally constructed to re-create the ambiance of the ancient period. Although this genre has no precedent in history, it is well accepted as an authentic religious code of Hinduism by religious as well as secular communities. Just as the use of NSA languages was authenticated by the religious scriptures composed by the mystics in NSA languages in the medieval period, the use of the Sanskrit mixed with Hindi and of Sanskrit and NSA language mixing in secular advertisements is authenticated and institutionalized by their presentation on television (for further discussion on authority in religious language, see Pandharipande, 2006).

Script as a Determinant of Religious Language

Some South Asian languages of religions are written in more than one script. For example, Panjabi and Sindhi are written in both Devanagari and Perso-Arabic scripts; Kashmiri has three scripts (Sharada, Devanagari, and Perso-Arabic); Maithili has two scripts: Devanagari and Kaithi; Konkani has three scripts: Devanagari, Roman, and Kannada. This situation raises the question of the choice of the script for a particular religious language.

Although a definite correlation between a script and religion in South Asia does not always exist, some correspondences are generally observed. Devanagri, due to its historical connection with Sanskrit, the language of the ancient Hindu scriptures, is traditionally associated with Hinduism. However, it is important to note that it is neither used exclusively for Hinduism, nor is it the only script used for the language of Hinduism. Many translations of the Bible in Devanagari are currently used in Christian churches. Moreover, the scripts of NSA languages (Tamil, Malayalam, Telugu, Bangla, Kannada, Gujarati) are used to express Hinduism. The interesting point is that Devanagari is generally chosen for Hinduism if the religious language has other scripts such as Perso-Arabic or Roman. For example, the Perso-Arabic script marks the identity of Islam in Kashmir, i.e., Kashmiri religious literature of Islam is written in the Perso-Arabic script, while the Devanagari script is identified with Hinduism, i.e., the Kashmiri Hindu scriptures were written in the Devanagari script at one point in time.

However, Pushp (1996: 22) points out that the Hindu religious texts such as the Upaniṣads, the epics (the *Rāmāyaṇã* and the *Mahābhārata*) were rendered in the Persian script as well. In contemporary South Asia, the distinction between Hindi and Urdu is to a large extent based on the difference in the scripts. While Hindi in the Devanagari script is the marker of Hinduism, Urdu with the Perso-Arabic script has become the pan-South-Asian Islam. Similarly, the Devanagari script differentiates Hindu

Konkani from Christian Konkani in Goa, which uses the Roman script (see Miranda, 1978).

An interesting situation is noted with the script of the languages of Sikhism. It is the Gurumukhi script and not the language that is the differentia of the religious literature. While the *Ādi Granth* (the oldest scripture of Sikhism) is in the Panjabi and Old Hindi mixed language, the Sikh religious literature from the 17th–19th centuries is in Braj Bhāṣā. Modern Panjabi is becoming the language of contemporary Sikhism. Despite the diversity of languages, the Sikh literature (in all of the above languages) is typically recorded in the Gurumukhi script. While the Perso-Arabic script is generally associated with Islam, the correlation between the two is not invariable. Muslims in Bengal prefer to use the Bangla script over Perso-Arabic to write Bangla. Similarly, the Ismāīlī Muslims use Gujarati (language and script), which has replaced the earlier script derived from Sindhi. While the Devanagari script is accepted as the script of the canonical Buddhist scriptures in India, Sri Lanka, and Tibet, the use of the Tibetan script is most common in Tibet. Similarly, while the Devanagari script is well accepted for Jainism, other scripts such as Kannada and Telugu are very commonly used as well.

In general, when more than one script is used, there is digraphia. While one script indicates the pan-South-Asian identity of the religion, the other script or scripts indicate the regional and religious identity. For example, the Devanagari script indicates the pan-South Asian Hindu identity, other scripts (of the regional languages) indicate regional Hindu identity. Similarly, the Perso-Arabic script indicates the pan-South-Asian Muslim identity, while other scripts indicate the regional identity (Bangla, Gujarati, etc.). While the Roman script symbolizes Christian identity, other South Asian scripts indicate South Asian and regional Christian identities. Devanagari identifies pan-South-Asian Hindu, Buddhism, and Jainism; other scripts symbolize their regional variants.

Contributions of the Religious Language to Linguistics

The study of religious language in South Asia has made significant contributions to the field of linguistics in four major areas: (a) language analysis (grammatical tradition), (b) theory of translation, (c) literary criticism, and (d) language contact, ideology, convergence, and identity. In the preceding sections, the discussion has focused on (c) and (d). This section will primarily concentrate on (a) and (b).

Grammatical Tradition

The impetus for language study, i.e., phonetics, grammar, and metrics came from the religious goal of understanding the scriptures (the *Vedas,* which were perceived as the repository of all knowledge). *Vyākaraṇa* 'grammar' was considered one of the auxiliary disciplines (*Vedānga*) for the proper study of the *Vedas*. Pāṇini (*see* **Panini**), in his monumental treatise on Sanskrit grammar, claims that the immediate purpose of grammar is to provide principles that distinguish correct forms from incorrect ones. However, Patanjali (*see* **Patanjali (2nd Century B.C.)**) in *his Mahābhāṣya* 'the great commentary' claims the following as the goals of grammar: (a) *rakṣā*, preservation (in their pure form) of the scriptures, transformation of inflectional affixes appropriately for the religious ritual context (*ūha*), correct recitation of the scriptures, (*āgama*), a simple way of language learning (*laghu*), disambiguating meaning of words beyond doubt (*asaṃdeha*). Pāṇini's grammar presents a systematic, complete, and theoretically consistent analysis of the Sanskrit language. Modern linguistics acknowledges *Aṣṭādhyāyī* as "the most complete generative grammar of any language yet written" (Kiparsky, 2001: 384). Pāṇini's grammar provided a descriptive mechanism and analytical tools for the later grammars of vernacular languages in South Asia, and for comparative linguistics in the 18th century after the discovery of Sanskrit by William Jones. The system of classification of the language into four groups, i.e., (a) *Aṣṭādhyāyī,* (b) *Śivasūtras* (an inventory of phonological segments), (c) *Dhātupāṭha* (a list of 2000 verbal roots), (d) *Gaṇapāṭha* (a list of lexical items that follow rules without a clear logic of the system) became the basis for describing South Asian languages. Furthermore, the division of the 4000 grammatical rules into metarules (*paribhāṣā*) and operational rules (*vṛtti*) and the concept of the domain of their operation (*adhikāra*) are some of the most significant insights that modern generative grammar owes to *Aṣṭādhyāyī*.

Additionally, the debates regarding the inherent (*Vedānta* school of Hinduism) vs. conventional relationship (*Nyāya-Vaiśekika* school) between word and meaning were rooted into the philosophical (and religious) conceptualizations of the world and language. Moreover, the controversies regarding the nature of (*Vedic*) language and its cognition clearly show that the study of language was largely influenced by views of (ultimate) reality and the role of language in understanding it, thereby accomplishing the goal of life. For example, while the unit of linguistic analysis was viewed by both the Vedāntins and the Pūrvamīmāṃsakas, as *vākya* 'sentence,' the Vedāntins considered language as assertive of facts (from which the knowledge of the physical and the ultimate transcendent reality [*Brahman*] could be gained), while the Pūrvamīmāṃsakas viewed it as injunctive (from which the knowledge of the accurate performance of the Vedic

rituals could be obtained). For the Vedāntins, *Brahman* was perceived as one indivisible reality, which is revealed in all aspects of the phenomenal world, and language (with its diverse components) represents the phenomenal reality, which reveals the ultimate one. Bhartṛhari (*see* **Bhartrhari**), a 6th century C.E. Vedāntin, proposed that the meaning (of a sentence) is an indivisible and noncomponential linguistic symbol *sphoṭa* (literally, that which bursts forth) that is revealed through, but not divided into words. The cognition of the meaning of a sentence is not sequential (i.e., word by word), rather, it is sudden (*sphoṭa*), similar to the recognition of *Brahman*, which is revealed through the multifaceted reality. Thus language study was embedded within the larger goal of life (to understand the ultimate reality).

In contrast to this, the Pūrvamīmāṃsakas perceived the ultimate reality as componential, and language representing it as componential as well. Their theory of cognition of sentence meaning was that the sentence meaning is divided into word meanings, the sequential cognition of which leads to the understanding of the sentence meaning (for further discussion, see Matilal, 1990).

Another example of the impact of the religious goal on the study of language is the Christian missionaries in South Asia, who wrote grammars of regional languages for the purpose of the Bible translation from English into South Asian languages. The grammars written by the missionaries (for example, the Baptist missionary William Carey's grammars of Marathi and Bengali) mark a major turn in the South Asian grammatical tradition. They analyzed South Asian languages within the framework of Latin and English grammars. These two distinctly different grammatical traditions (Hindu and Christian) have coexisted in South Asia until recently. The Sanskrit and the Latin/English grammatical systems, in their effort to fit the South Asian languages into their respective molds, have failed to take into account their distinctive sociocultural and linguistic character.

The need to constantly evaluate and standardize the Bible translations into languages of the world (including South Asian languages) led the British and Foreign Bible Society (1804) and the American Bible Society (1816) to promote the study of the South Asian languages in their cultural context. Under the influence of modern descriptive linguistics in America, Kenneth Pike and Eugene Nida of the Summer Institute of Linguistics (SIL; established in 1934), the methods of applied linguistic analysis were applied to minority languages across the world including South Asia.

The grammars produced by the SIL show more culturally sensitive analysis of South Asian languages compared to the grammars of the missionaries in the 19th century. The surveys conducted by the SIL to access the patterns of language use are extremely useful for sociolinguistic studies on literacy, multilingualism, and second language proficiency. A notable survey is the *Survey of northern Pakistan*, a joint publication of SIL and the National Institute of Pakistan Studies of the Quaid-I-Azam University (O'Leary, 1992).

Translation

Bible translations in South Asian languages have contributed to the theory of translation. The issue of defining translation equivalence (though ignored in the early 19th century) was raised in the SIL. The relative importance of structural, semantic, and functional equivalence in translation was systematically discussed in Nida (1964) (*see* **Nida, Eugene Albert (b. 1914)**). One of the richest areas of research in South Asian languages of religion is the translation of the sacred texts of Hinduism. While almost all of the major scriptures (the *Vedas*, the *Upaniṣads*, the epics, the *Bhagavadgītā*) are translated and 'transcreated' in the regional languages, not much attention has been paid to the authenticity of translation. The authenticity of the religious text (original or translated) has always been determined (in the history of Hinduism) by the religious authority of the translator (for example, if the translator is a saint/mystic, then the translation is viewed as authentic). The Hindu tradition has not discussed the issue of standardization of translation of scriptures independently of the translator. In fact, the language of the saints and the mystics of the 15th–20th centuries became the standard for the tradition, which has treated translation as a strategy to contextualize the eternal truth for the particular community at a particular time and place.

As noted earlier, Islam and Sikhism do not treat translations of their respective original scriptures (Qur'an and Granth) as scriptures, while Buddhism, similar to Hinduism, treats the religious authority of the translator as the parameter for judging authenticity of the translated text.

The View of Language

The beliefs about language presented in the Pali canon of Buddhism, Tripitaka 'the three baskets' (which is the scripture of the Theravāda (the instruction of the elders) branch of Buddhism) explain why Buddhism in South Asia (as well as in other parts of the world) does not restrict transmission of religion to one language.

It is difficult to extract the exact words of the Buddha due to the oral tradition. Therefore, we rely on the teaching of the Buddha to understand his views on language. The Buddha did not accept any

inalienable relationship between a word (linguistic form) and its referent (function or meaning). According to the Four Noble Truths of Buddhism, it is the impermanence of phenomena, and the attachment to the impermanent is believed to be the cause of suffering. Language, similar to other phenomena, is impermanent/conventional. The relationship between the linguistic form and meaning (function) is conventionally determined. The same meaning can be expressed in different forms. The Buddha did not accept the privileged position of Sanskrit and allowed the use of dialects for the religious discourse. Buddha himself used a Middle Indo-Aryan dialect (Magadhi), which later came to be identified as Pāli. Language was viewed as an impermanent tool to convey the Four Noble Truths. Therefore, one should not be attached to it. What made language meaningful was the experience of the speaker. The early Buddhist teaching was in Pāli, while the later Buddhist texts around the beginning of the Christian Era, such as *Mahāvastu*, (of the Mahāsānghika Lokottaravādin sect), and the *Saddharmapuṇḍrika Sūtra* (the Lotus Sūtra of the Mahāyāna sect) were composed in Sanskrit (Buddhist Hybrid Sanskrit; Edgerton, 1953), which showed influence of contemporary vernacular Middle Indo-Aryan dialects. The hybrid Sanskrit does not fully adhere to Pāṇini's (5th century B.C.E.) rules of grammar. In contemporary South Asia, regional languages are used for the transmission of Buddhism.

Conclusion

The present discussion points out that in a multilingual and multireligious region such as South Asia, the choice of a language to express a religion is determined by the ideology concerning the function of the religious language and the relative power of the language(s) to carry out that function. It also demonstrates that the ideology changes across time, which restructures the hierarchy of power of languages and consequently affects the choice of languages for expressing religions. It is further shown that the ideology is implemented through two mechanisms: authority and the degree of functional transparency of the language. Therefore, ideology, authority, and functional transparency should be treated as mechanisms of change in the structure and function of religious languages in particular, and languages in general. Furthermore, the discussion shows that the same ideology can be expressed in two mutually exclusive and at least apparently opposite processes. For example, the ideology of using NSA languages for religious expression (in the medieval period) was expressed in two linguistic processes of Sanskritization and de-Sanskritization. This challenges the current theory of ideology that assumes that one ideology is realized in promoting only one structural realization.

The discussion shows that authority is not static: it changes over time. Moreover, even if the authority remains the same, it licenses different ideologies at different points in time.

It is argued with evidence that when one language is used for different religions, its linguistic form will change (recall the various registers of Hindi). Similarly, when one religion is expressed in many languages, the religious content changes as well. In particular, it is shown that the use of the NSA languages to express religion has produced convergence of NSA languages across language families. This is an interesting case of linguistic convergence of languages through the development of shared religious registers (Sanskritized), where languages (of Indo-Aryan and Dravidian families) converge via Sanskrit without direct mutual contact. A similar case of convergence of NSA languages is seen in their anglicization (in contemporary South Asia), which results in the emergence of anglicized registers of NSA languages. What is different about this convergence is that the converging languages are not necessarily in contact with each other.

The concept of heteroglossia explains the choice of a language in modern South Asia, and, more importantly, it demonstrates that distribution of languages is in a multilingual society is not always explicable on the basis of diglossia where the choice of a code is determined by the social domain of language use. It is argued that the choice is determined by the religious and social identity that is intended to be expressed by the language.

Finally, the discussion shows that the sociolinguistic conditions (the ideology, authority, and functional transparency of the code) that determine a code as a language of religion may change at different points in time.

Figure 14 summarizes the discussion on the choice of the code for expressing a religion at three major points in time. In the first period, the form, content, and function are viewed as invariable since the languages chosen for expressing religions at this time are the classical languages or the languages of the scriptures.

In the medieval period (column II), the ideology changed, allowing variation in the form and keeping the content perceived as invariable. As long as the religious content was maintained, the form that expressed that content was perceived as religious. The function of the religious language also remained the same as before. The NSA languages (along with the earlier classical/scriptural languages) were chosen as religious languages. Diglossia was the mechanism that allowed maintenance of both the classical and

Figure 14 The choice of the code for expressing a religion at three major points in time. + indicates nonvariability; – indicates variability.

the NSA languages. In the third (contemporary) period (see column III), the choice of the language for expressing a religion is determined by the identity of the religion or community. The form, content, and function are variable, thus allowing languages to cross over the religions as well as the boundaries of the secular and the sacred.

This framework illustrates that different religious communities and cultures may vary in their ideology concerning the composition of the three components of the language of religion, and thereby the choice of the religious codes may vary as well.

Some Issues in Languages of Religion in South Asia

The discussion in the preceding sections shows that sociopolitical conditions contributed to the emergence of multiple linkages of languages and religions. However, in order to fully understand the social and linguistic dynamics of the multiple linkages, it is necessary to understand the issues related to translation of religious texts from one language into another, the transcreations of the religious texts into different languages, and the relationship between the linguistic form and its social function. Some of the major issues are: (a) how does the target language (i.e., the language into which the text is being translated) accommodate the new religious content? In other words, what linguistic strategies or mechanisms are used for this process of establishing a new alignment of the linguistic form with the function/meaning? (b) Which rationale authenticates the change, and what are the social and religious practices that promote acceptance of this change?

The language of religion in South Asia provides a rich ground for cross-linguistic, cross-cultural, and cross-religious studies, which have only just begun (see, Pandharipande, 2006).

South Georgia and South Sandwich Islands: Language Situation

Editorial Team

© 2006 Elsevier Ltd. All rights reserved.

South Georgia and the South Sandwich Islands are situated in the southern sector of the Atlantic Ocean, some 1400 km east of the Falkland Islands. With the exception of a brief period during the Falklands War in 1982, when Argentina occupied them, the islands have been under British administration since 1908. There is no indigenous population and the only permanent settlement is on South Georgia, where a group of scientists from the British Antarctic Survey has had its base since March 2001, when it took the base over from a small military garrison that had been posted there after the Falklands War. The British Antarctic Survey also has a biological station on Bird Island, off the northwest end of South Georgia. The South Sandwich Islands are completely uninhabited. South Georgia and the South Sandwich Islands are an overseas territory of the United Kingdom, also claimed by Argentina. They are administered from the Falkland Islands by a commissioner representing the British government. The laws of the United Kingdom apply on the islands and English is the official language – the islands' motto is, however, in Latin: *leo terram propriam protegat* (let the lion protect its own land).

South Georgia and South Sandwich Islands: Language Situation

Editorial Team

© 2006 Elsevier Ltd. All rights reserved.

South Georgia and the South Sandwich Islands are situated in the southern sector of the Atlantic Ocean, some 1400 km east of the Falkland Islands. With the exception of a brief period during the Falklands War in 1982, when Argentina occupied them, the islands have been under British administration since 1908. There is no indigenous population and the only permanent settlement is on South Georgia, where a group of scientists from the British Antarctic Survey has had its base since March 2001, when it took the base over from a small military garrison that had been posted there after the Falklands War. The British Antarctic Survey also has a biological station on Bird Island, off the northwest end of South Georgia. The South Sandwich Islands are completely uninhabited. South Georgia and the South Sandwich Islands are an overseas territory of the United Kingdom, also claimed by Argentina. They are administered from the Falkland Islands by a commissioner representing the British government. The laws of the United Kingdom apply on the islands and English is the official language – the islands' motto is, however, in Latin: *leo terram propriam protegat* (let the lion protect its own land).

Introduction

South Philippine languages form one of three major language groups found in the Philippines, all of which belong to the Western Malayo–Polynesian branch of the Austronesian family. The South Philippine language family includes the Subanon, the Danao, and the Manobo subgroups. The Subanon subgroup is spoken on the Zamboanga peninsula of Mindanao, the Danao subgroup is spoken in central Mindanao, and the Manobo subgroup is spoken in central and eastern Mindanao. Two other groups of languages spoken in the Philippines are not South Philippine languages but are more likely related to languages of Indonesia and Malaysia. These languages, found in the southern Philippines, are the South Mindanao languages, spoken in southern Mindanao, and the Sama languages, spoken on the Zamboanga peninsula and the Sulu Archipelago (see Table 1).

Although considerable research has been devoted to identifying and grouping languages of the southern Philippines, less effort has been spent on describing the grammar of these languages. Most of the available descriptions, completed in the 1960s and 1970s, emphasized phonology, verb morphology, sentence structure, and discourse features. A number of important findings from cross-linguistic studies in the 1980s resulted in significant reanalyses of the basic verbal sentences of Philippine languages. The outcome is that the sentence type traditionally called the 'goal-focus' construction was confirmed to be the basic transitive sentence. Later studies have also suggested that the 'actor-focus' construction is not one but two distinct sentences types: an active intransitive sentence (in which the verb is semantically intransitive) and an antipassive construction (in which the verb is semantically transitive). The few descriptions of languages in the southern Philippines completed after the 1970s generally reflect these reanalyses and also provide more information about syntactic processes, giving attention to the function and behavior of constructions as well as their structure.

In the following discussion, grammatical relations are labeled as follows: the only grammatical relation of a single-argument sentence is S, the more agent-like grammatical relation of a transitive sentence is A, and the less agent-like grammatical relation of a transitive sentence is O. Case markers are morphemes that formally distinguish between A and O in a transitive sentence. These markers form three patterns: nominative–accusative (henceforth 'nominative'), ergative–absolutive (henceforth 'ergative'), and tripartite. In the nominative pattern, S and A are marked the same, but O is marked differently; in the ergative (ERG) pattern, S and O are marked the same, but A is marked differently; in the tripartite pattern, S, A, and O are each marked differently. In a split ergative pattern, S, A, and O display ergative case

Table 1 South Philippine, South Mindanao, and Sama languages[a]

South Philippine	*South Mindinao*	*Sama*
Subanon subgroup	Bilic	Sama
Eastern Subanun – Central Subanen, Northern Subanen, Lapuyan Subanun	Blaan – Koronadal Blaan, Sarangani Blaan	Sibuguey Sama, Northern Sama, Western Sama, Central Sama, Southern Sama
Kalibugan – Kolibugan Subanon, Western Subanon	Tboli	Yakan
Danao subgroup	Tiruray	Yakan
Maguindanao – Maguindanaon	Tiruray	Jama Mapun
Maranao-Iranon – Ilanun, Maranao	Bagobo	Jama Mapun
Manobo subgroup	Giangan	Abaknon
North Manobo – Binukid, Higaonon, Kagayanen, Cinamiguin Manobo		Abaknon
Central Manobo		
East Central Manobo – Agusan Manobo, Dibabawon Manobo, Rajah Kabunsuwan Manobo		
South Central Manobo – Obo Manobo		
Ata-Tigwa – Ata Manobo, Matigsalug Manobo		
West Central Manobo – Ilianen Manobo, Western Bukidnon Manobo		
South Manobo – Cotabato Manobo, Sarangani Manobo, Tagabawa Manobo		

[a]Based on data from McFarland (1980).

marking in some sentences and nonergative case marking in others. If S, A, and O are all marked the same, the forms are said to be neutralized for case.

Phonology

South Philippine, South Mindanao, and Sama languages have relatively straightforward phonemic inventories. Vowel systems have four, five, six, or, more rarely, seven vowels. Consonants consist of voiced and voiceless stops (including glottal stop), a few fricatives (often /s/ and /h/), nasals, /l/ and a rhotic (which, depending on the language, is a flap, /ɾ/ or /ɽ/, or a trill, /r/), and the semivowels /w/ and /j/. Some of the Sama languages also have /d͡ʒ/. Long vowels and geminate consonants are common. Word stress occurs on the penultimate or, less commonly, the ultimate syllable and may or may not be predictable, depending on the language.

In the Subanon and Manobo subgroups and in the Sama languages, intervocalic consonants (C), particularly /l/, tend to be deleted over time. This appears to be the source for two common phonological features noted in these languages: long vowels (V) and the syllable V(C). In a significant number of Philippine languages, an epenthetic glottal stop is inserted in syllable onsets (but not codas) when no other phonetic material is available; however, this strategy is apparently not available when an intervocalic consonant is lost in these languages. Thus, the loss of an intervocalic consonant opens a pathway for the resulting sequence of vowels to become long vowels or to coalesce into a new vowel: e.g., /o/ + /i/ → /e/ in Obo Manobo (Khor and Vander Molen, 1996: 31) and /aː/ + /i/ → /æ/ and /a/ + /u/ → /ɔː/ in Northern Subanen (Daguman and Sanicas-Daguman, 1997: 103). The loss of /l/ or some other intervocalic consonant also seems to be the source for word-medial V(C) syllables, also noted for Subanon and Manobo subgroups and Sama languages. Only Maguindanaon allows a word-initial V(C) syllable (the facts are not available for Maranao). Thus, syllable types for Maguindanaon, Obo Manobo, Northern Subanen, and Southern Sama are CV(C) and V(C).

On the other hand, the loss of a mid-central vowel in the South Mindanao subgroup has led to the development of word-initial CCV(C) syllables. For Tboli, the loss appears to have occurred in words beginnings with CV syllables. For Blaan, it occurred in words beginning with CVC syllables. This claim is based on the fact that in Tboli, a mid-central vowel can be inserted optionally after the first consonant of the root (e.g., *btang* ~ *betang* 'to fall') (Forsberg, 1992: 6), but in Blaan, the mid-central vowel is inserted optionally before the first consonant of the root (e.g., *bgang* ~ *ebgang* (adj.) 'broken') (Sally Winter, personal communication). Thus, syllable types for South Mindanao languages are CV(C) and CCV(C). Word-initial CCV(C) syllables also occur in Maranao but are limited to homorganic nasals followed by stops: e.g., /mb/, /nd/, /ŋk/, /ŋg/ (no occurrences of /mp/ or /nt/ are listed in McKaughan and Al-Macaraya (1996)).

Three other phonological features are also notable. One is a unique set of phonological alternations triggered by the syntactic category marker *G-* in Subanon languages. These alternations involve change in voicing, nasalization, point of articulation, spirantization, and deletion of *G-*, depending on the identity of the following consonant (Sanicas-Daguman, 1996: 63–64) (see later, Morphology). The second notable feature is neutralization of contrast between /a/ and certain other vowels in Manobo languages. Specifically, in several Manobo languages, /a/ contrasts with all vowels only in the last two syllables of a word. It never occurs in any syllable to the left of the penultimate. When /a/ moves into one of these positions, it is replaced by one particular vowel: e.g., /a/ → /o/ in Obo Manobo (Khor and Vander Molen, 1996: 30), /a/ → /e/[ə] in Western Bukidnon Manobo (Elkins, 1963), and /a/ → /ɔ/ in Matigsalug Manobo (Elkins, 1984). The third feature is the tendency for high vowels in Maguindanaon to lose their moras under certain conditions, such that high vowels surface as palatalization and labialization on preceding consonants (if they are the first vowel in the sequence) or as glides of diphthongs (if they are the second vowel in the sequence) (Lee, 1964; Skoropinski, 2004).

Morphology

Morphology tends to be more complex in South Philippine languages than in South Mindanao and Sama languages. Taking verbal morphology as an example, South Philippine languages display a fairly extensive range of verbal affixes, some of which undergo complex phonological alternations. These affixes function as portmanteau morphemes, signaling a variety of syntactic and semantic information. The most common information is transitivity (intransitive vs. transitive), dynamism (dynamic vs. stative), and the semantic role of S or O. Aspect, mood, and, less commonly, tense are marked on the verb, but for at least one South Philippine language (Obo Manobo), a mood contrast (realis vs. irrealis) is signaled by clause-level clitics, as well as by verb affixes. Other types of information that may be marked on the verb are abilitative, habitual, reciprocal, distributive, and multiple participants. South Mindanao and Sama languages typically take fewer verbal affixes, and at

least some tense, aspect, and mood contrasts are indicated by words or clitics, rather than by verbal affixes. On the other hand, Sama languages gain in complexity through the ubiquitous presence of the affix *pa-*, which attaches to many verb stems and performs several functions. Most commonly, *pa-* creates new words and adds arguments to the sentence (e.g., an agent to a basic verbal sentence or a causer to a causative construction).

Three other morphemes are also of interest. The first is the Subanon syntactic category marker *G-*, undoubtedly the single most interesting morphophonological feature of this subgroup. The marker *G-* attaches to nouns and to all lexical constituents of noun phrases (NPs), marking the constructions as nominals. Evidence suggests that *G-* is the final consonant of an old case marker that over time became phonologically attached to the first consonant of the following nominal; it has subsequently been reanalyzed as a syntactic category marker, i.e., a nominal marker in the literal sense.

The second morpheme of note is the verbal affix *-an*. This affix occurs in most Philippine languages and functions as a valence increaser, i.e., it occurs on a verb when an oblique NP, usually a location, a recipient, or a beneficiary, is promoted to the O argument (direct object) (see later, Syntactic Processes). Although *-an* performs this function in certain Sama languages (Southern Sama and Balangingi Sama), in these languages it also has a second function – that of verb classifier. As a verb classifier, *-an* occurs on some but not all verbs when O is a patient (PAT). (For most semantically transitive verbs, a patient is the unmarked choice for O; consequently, *-an* cannot be functioning as a valence increaser when it cross-references an O patient.) Since *-an* occurs on some, but not all, verbs when O is a patient, it divides verbs into two classes, those that require *-an* when O is a patient and those that do not. This function of *-an* seems to be unique to the Sama subgroup.

The third morpheme is the Yakan clitic *-in*. This clitic occurs on NPs and nominalized sentences and has two functions. First, it signals that a nominal is definite (DEF). In Yakan transitive (TRANS) sentences, O must be definite but not A. Consider Example (1) (Brainard and Behrens, 2002: 42):

(1) tinnennun we′ dende bunga-samahin
-in-tennun we′ dende bunga-sama-in
TRANS-weave ERG woman *bunga-sama*.type-DEF
'a woman wove the *bunga-sama* type of weaving.'

Second, *-in* marks S of a single-argument sentence (i.e., term (TRM)), whether or not S is definite (Example (2)) (Brainard and Behrens, 2002: 52):

(2) lakkes kura′-in
fast horse-TRM
'a/the horse is fast.'

A phonologically identical morpheme that appears to have a similar function also occurs in Balangingi Sama (Gault, 1999: 18).

Morphosyntax of Basic Sentence Types

South Philippine, South Mindanao, and Sama languages display typical Philippine-type sentence structure: sentences are verb-initial and main verbs usually take an affix that cross-references one, and only one, NP in the sentence (i.e., S in a single-argument sentence and O in a transitive sentence). Sentences that express identity, attribute, possession, location, and existence are usually verbless. Sentences that express states may pattern like verbless sentences (in which case the state is coded as an adjective), or like verbal sentences (in which case the state is coded as a stative verb). Sentences that express actions are verbal sentences and are grouped into four types: active intransitive, transitive, antipassive, and passive. The active intransitive sentence has a semantically intransitive verb; all the other sentence types have semantically transitive verbs (or verbs that pattern like semantically transitive verbs).

In some Philippine languages, transitive sentences have two word orders: VAO and VOA. Traditionally, this pattern has been explained in terms of phonology (i.e., the phonologically shorter argument precedes the phonologically longer one) or in terms of morphology or topicality (i.e., a pronoun precedes a full NP); however, neither explanation has accounted for all the facts. Brainard and Vander Molen (2003) suggested that the VOA sentence is a word-order inverse (a voice construction first proposed by Givón (1994)). Selection of the VOA inverse construction over the VAO active construction is determined either by a person hierarchy (if only first and second persons are involved) or a topicality hierarchy (if only third persons are involved), or a combination of both hierarchies (if first, second, and third persons are all involved). If full NPs as well as pronouns are involved in the selection, then the hierarchy looks like that in Figure 1. In general, if A outranks O on the hierarchy, the VAO active construction is selected, but if O outranks A, the VOA inverse construction is selected.

First person > Second person > Third person > Pronouns > Full noun phrases

Figure 1 Person–topicality hierarchy governing VAO and VOA selection.

Antipassives and passives are detransitivized constructions, i.e., constructions in which one grammatical relation of a transitive sentence has been demoted to oblique or deleted. In Philippine antipassives, O of the transitive counterpart is demoted or deleted. Although the demoted NP is often indefinite, it may be definite. Following demotion or deletion of O, A becomes S. In a Philippine passive, A of the transitive counterpart is obligatorily deleted, and following deletion, O becomes S.

Two types of passives occur in Philippine languages: a morphological passive and a nonmorphological passive. In the morphological passive, the verb takes stative affixes, but in the nonmorphological passive, the verb takes the same affixes that occur on it in a transitive sentence. Thus, the only difference between a nonmorphological passive and a transitive sentence is the obligatory absence of A in the passive. As it happens, some Philippine languages have both types of passives. The factors determining the selection of one passive over the other appear to be language specific and have not yet been fully investigated.

With the identification of the goal-focus construction as the basic transitive sentence, case-marking patterns have undergone reexamination. In South Philippine and Sama languages, case marking displays either a consistently ergative pattern or a split ergative pattern (the precise details of the split ergative patterns vary from language to language). In South Mindanao languages, nominal markers do not function as case markers, although pronouns are marked for case.

At this point, it may be useful to compare actual data from representative languages. When discussing nominal markers, only the marking of S, A, and O will be considered.

Maguindanaon

Common nouns and personal names are marked for case and display an ergative pattern (see Table 2) (it is unclear if the VOA inverse is possible when A and O are both full NPs). Pronouns are also marked for case (see Table 3). In a VAO active construction, second-person pronouns have a tripartite pattern, but third-person pronouns have an ergative pattern. In a VOA inverse construction, second-person pronouns have an ergative pattern (for all other persons, either A or O does not occur in the construction). Maguindanaon has five types of verbal sentences: active intransitive, VAO active construction, VOA inverse construction, antipassive, and passive. Example (3) is an active intransitive sentence (Bruce Skoropinski, personal communication):

(3) lemu aku saguna
leave 1SG now
'I will leave now.'

Selection of a VAO active construction (Example (4); Bruce Skoropinski, personal communication) and a VOA inverse construction (Example (5); Fleischman, 1986: 30) is governed by a person–topicality hierarchy identical to that in Figure 1 (in the following examples, COMP means 'completed aspect'):

(4) in-umbal-an ku seka sa liplanu
COMP-make-BEN 1SG 2SG OBL airplane
'I made you an airplane.'

(5) in-enggat aku nengka kanu walay nengka
COMP-invite 1SG 2SG OBL house GEN.2SG
'you invited me to your house.'

Example (6) (Fleischman, 1986: 30) is the antipassive. (Example (7) is its transitive counterpart.)

(6) min-umbal aku sa liplanu sa leka
COMP-make 1SG OBL airplane OBL OBL.2SG
'I made an airplane for you.'

(7) in-umbal ku su liplanu sa leka
COMP-make 1SG ABS airplane OBL OBL.2SG
'I made the airplane for you.'

The Maguindanaon passive is a nonmorphological passive. Compare the passive in Example (8) (Bruce Skoropinski, personal communication) with its transitive counterpart in Example (6):

Table 2 Maguindanaon case markers

Noun type	*Marker*		
	S	*A*	*O*
Common nouns			
Definite	su	nu	su
Indefinite	i	na	i
Personal names	si	ni	si

Table 3 Maguindanaon pronouns

Person/ number	*VS sentence, S*	*VAO sentence*		*VOA sentence*	
		A	*O*	*O*	*A*
Singular					
1	aku	ku	–	aku	–
2	ka	nengka	seka	ka	nengka
3	sekanin	nin	sekanin	–	nin
Plural					
1INCL	tanu	tanu	–	tanu	–
1DU	ta	ta	–	ta	–
1EXCL	kami	nami	–	kami	–
2	kanu	nu	sekanu	kanu	nu
3	silan	nilan	silan	–	nilan

(8) in-umbal su liplanu sa leka
COMP-make ABS airplane OBL OBL.2SG
'the airplane was made for you'

Obo Manobo

Obo Manobo has two types of transitive sentences, a VAO active construction and a VOA inverse construction. Case marking of common nouns and personal names in both constructions is identical and displays a consistently ergative pattern (see Table 4). Pronouns are also case marked (see Table 5). In a VAO active construction, first- and second-person pronouns have a tripartite pattern and third-person pronouns have an ergative pattern. On the other hand, in a VOA inverse construction, first-person plural exclusive pronouns and second- and third-person pronouns have an ergative pattern. (The pronouns *nikoddi* '1SG' and *niketa* '1PL.INCL' have recently come to notice and also appear to be possible for A in VOA constructions, although this needs to be confirmed.) Obo Manobo has six types of verbal sentences: intransitive, VAO active construction, VOA inverse construction, antipassive, morphological passive, and nonmorphological passive. Example (9) (Edna Vander Molen, personal communication) is an active intransitive sentence:

(9) od usok ka diyon to baoy
IRR enter 2SG there OBL house
'you will enter into the house'

Table 4 Obo Manobo case markers

Noun type	*Marker*		
	S	*A*	*O*
Common nouns			
Definite	idda (so)	(tadda) to	idda (so)
General	ko/do	to	ko/do
Specific	ko (so)/do (so)	to	ko (so)/do (so)
Personal names			
Singular	si	ni	si
Plural	onsi	onni	onsi

Examples (10) and (11) (Vera Khor, personal communication) show, respectively, a VAO active construction and a VOA inverse construction:

(10) od suntuk-on din sikkow
IRR hit-PAT 3SG 2SG
'he will hit you'

(11) od suntuk-on ka nikandin
IRR hit-PAT 2SG 3SG
'he will hit you'

Selection of the active construction and the inverse construction is controlled by a person–topicality hierarchy identical to that in Figure 1. Obo Manobo is notable in that both constructions are possible for most person combinations. Word-order inverses have also been noted for Agusan Manobo, Matigsalug Manobo, Sarangani Manobo, Tagabawa Manobo, and Western Bukidnon Manobo. Example (12) is the antipassive. (Example (13) is its transitive counterpart (Ena Vander Molen, personal communication):

(12) od tampod iddos anak to tali
IRR cut ABS child OBL rope
'the child will cut a rope'

(13) od tompoddon to anak iddos tali
od tampod-on to anak iddos tali
IRR cut-PAT ERG child ABS rope
'the child will cut the rope'

Examples (14) and (15) (Ena Vander Molen, personal communication) are, respectively, a morphological passive and a nonmorphological passive (Example (13) is the transitive counterpart):

(14) od ko-tampod iddos tali
IRR PASS-cut ABS rope
'the rope will be cut'

(15) od tompoddon iddos tali
od tampod-on iddos tali
IRR cut-PAT ABS rope
'the rope will be cut'

Table 5 Obo Manobo pronouns

Person/number	*VS sentence, S*	*VAO sentence*		*VOA sentence*	
		A	*O*	*O*	*A*
Singular					
1	a	ku	siyak	a	–
2	ka	du/ru	sikkow	ka	nikkow
3	sikandin	din/rin	sikandin	sikandin	nikandin
Plural					
1INCL	ki	ta	siketa	ki	–
1EXCL	koy	doy/roy	sikami	koy	nikami
2	kow	dow/row	sikiyu	kow	nikiyu
3	sikandan	dan/ran	sikandan	sikandan	nikandan

Tboli

Tboli common nouns and personal names are not marked for case, but pronouns are and display a split case-marking system (see Table 6) (some pronouns have allomorphs, not all of which are listed in Table 6). The first split occurs between singular and plural forms. Singular forms have a tripartite pattern. The second split occurs between plural forms: all plural forms except first-person inclusive have a nominative pattern, and first-person inclusive forms are neutralized for case. Table 6 shows the distribution of pronouns in affirmative sentences. A notable feature of Tboli is that the negation of a sentence triggers a change in pronoun sets for S and O. This change also alters the case-marking pattern slightly (see Table 7). In negated sentences, singular first and second persons still display a tripartite pattern, but singular third persons now display a nominative pattern. All other persons except first-person plural inclusive continue to display a nominative pattern; first-person plural inclusive continues to be neutralized for case (the alternation of pronouns in affirmative and negated sentences does not occur in Blaan). Examples (16)–(19) illustrate the changes in pronouns. When a single-argument sentence is negated, S changes only when it is a singular third person (Examples (16) and (19) from Lillian Underwood (personal communication); Examples (17) and (18) from Forsberg (1992: 101, 102)):

(16) mung-e
go-1SG
'I'm going along'

(17) là mung-e
not go-1SG
'I'm not going along'

(18) mung
go
'he is going along'

(19) là mung-en
not go-3SG
'he is not going along'

When a transitive sentence is negated, O changes when it is any person except third-person singular and first-person plural inclusive (Examples (20) and (21); Porter, 1977: 114, 115):

(20) nwit Kasi ou elem bulul
TRANS.take Kasi 1SG to mountains
'Kasi took me to the mountains'

(21) là nwit Kasi dou elem bulul
not TRANS.take Kasi 1SG to mountains
'Kasi didn't take me to the mountains'

As might be expected, word order is relatively rigid and a primary means of distinguishing between A and O in transitive sentences; however, when S, A, or O is an expanded full NP, the NP moves to the end of the sentence, and a coreferential pronoun is left in the normal sentence position (Example (22); Forsberg, 1992: 57) (in the following example, PREP means 'preposition'):

(22) kól le$_i$ bélê me
arrive 3PL PREP 1PL.EXCL
[kem tau dmadu]$_i$
PL person INTRANS.plow
'the men who are to plow have arrived to us'

If both A and O are expanded NPs, both NPs move to the end of the sentence, with A coming last. Coreferential pronouns are left for A and O in their normal positions (Example (23); Porter, 1977: 99) (in the following example, SPEC means 'specific'):

Table 6 Distribution of pronoun sets in affirmative Tboli sentences[a]

Pronoun	*Person/number*		
	S	*A*	*O*
Singular			
1	-e	-u	ou/o
2	-i	-em	uu/u
3	ø	-en	du
Plural			
1INCL	tekuy	tekuy	tekuy
1DU	te	te	tu
1EXCL	me	me	mi
2	ye	ye	yu
3	le	le	lu

[a]Based on data from Forsberg (1992: 22), with permission.

Table 7 Distribution of pronoun sets in negated Tboli sentences

Pronoun	*Person/number*		
	S	*A*	*O*
Singular			
1	-e	-u	dou/do
2	-i	-em	kóm
3	-en	-en	du
Plural			
1INCL	tekuy	tekuy	tekuy
1DU	te	te	kut
1EXCL	me	me	kum
2	ye	ye	kuy
3	le	le	kul

(23) eted le$_i$ lu$_j$ [yó kem
deliver 3PL 3PL SPEC PL
ngà lemnek]$_j$ [yó kem
child small SPEC PL
tau lemwót gu leged]$_i$
person INTRANS.come from upstream
'the people from upstream delivered the small children'

If only one expanded NP is present at the end of a transitive sentence, it always refers to O (Example (24); Porter, 1977: 98):

(24) eted le lu$_i$ [yó kem ngà lemnek]$_i$
deliver 3PL 3PL SPEC PL child small
'they delivered the little children'

Expanded NPs in Blaan do not change sentence position.

Southern Sama

Southern Sama common nouns and personal names display a consistently ergative case-marking pattern. For common nouns and personal names, S and O have no case marker, but A is obligatorily marked by *heh*. For pronouns, all persons except plural third persons display an ergative pattern (see Table 8). Plural third-person pronouns are neutralized for case. Note that phonological contrast is minimal for first-person plural exclusive: S, A, and O are identical except for word stress (represented in Table 8 by an acute accent). When A is a pronoun in a transitive sentence of type 1 (see Examples (26) and (27)), it is also obligatorily marked by *heh*. Southern Sama has five types of verbal sentences: active intransitive, transitive type 1, transitive type 2, antipassive, and passive. Example (25) is an active intransitive sentence (Trick, 1997: 126):

(25) pasód anak-anak ni lumah
enter child OBL house
'the child will enter into the house'

Table 8 Southern Sama pronouns

Pronoun	*Person/number*		
	S	*A*	*O*
Singular			
1	akú	ku	akú
2	kow	nu	kow
3	iyá	na	iyá
Plural			
1INCL	kitabí	tabí	kitabí
1DU	kitá	ta	kitá
1EXCL	kamí	kámi	kamí
2	kam	bi	kam
3	sigá	sigá	sigá

Transitive sentences are of two types. Transitive sentence type 1 is more morphologically complex, compared to type 2, because the verb must occur with the affix *ni-* (or its allomorph *-in-*), A is either a full NP or a pronoun and must be preceded by the ergative marker *heh*, and word order may be VAO or VOA, with VOA being the more common order (transitive type 1, Examples (26) and (27), VOA and VAO order, respectively; Trick, 1997: 128):

(26) sinampak eroh heh anak-anak
sampak-in- eroh heh anak-anak
slap-TRANS dog ERG child
'the child will slap the dog'

(27) sinampak heh anak-anak eroh
sampak-in- heh anak-anak eroh
slap-TRANS ERG child dog
'the child will slap the dog'

Transitive sentence type 2 is morphologically simpler: the verb never occurs with *ni-*, A must be a pronoun and is never preceded by *heh*, and word order is obligatorily VAO (Example (28); Doug Trick, personal communication) (similar pairs of transitive sentences have also been noted for Balangingi Sama, Pangutaran Sama, and Yakan):

(28) sampak-ku eroh
slap-ERG.1SG eroh
'I will slap the dog'

Example (29) (Trick, 1997: 132) is the antipassive. (Example (30) (Trick, 1997: 132): is its transitive counterpart.)

(29) ngan-dugsuh aku sowa
AGT-stab ABS.1SG snake
'I will stab a/the snake'

(30) ni-dugsu-an sowa heh-ku
TRANS-stab-PAT snake ERG-ERG.1SG
'I will stab the snake'

Passive sentences in Southern Sama are nonmorphological passives (Example (31); Trick, 1997: 133); compare Example (31) with its transitive counterpart, Example (29):

(31) ni-dugsu-an sowa
TRANS-stab-PAT snake
'the snake will be stabbed'

Syntactic Processes

Although syntactic processes have been investigated in a few languages, e.g., Sama, Yakan, and Northern Subanen, this is an area of Phillipine linguistics that still needs more research. What has been noted to date is that South Philippine, South Mindanao, and Sama languages, like all Philippine languages, allow

an oblique NP to be promoted to O (i.e., direct object), although languages vary as to which semantic roles may undergo promotion. The promoted NP is always cross-referenced by an affix on the verb. A variation of this process occurs in some Sama languages. In cleft constructions in Philippine languages, S and O are the only arguments eligible to be the head of the construction, in which case they are usually cross-referenced by a verbal affix. For certain verbs, however, the verbal affix may cross-reference an oblique NP. For these NPs, morphological and syntactic evidence shows that the cross-referenced NP has changed its relation to the verb, but has not become a grammatical relation (i.e., O). (This process has been noted for Southern Sama and Yakan. In Southern Sama, a similar process also occurs in antipassive constructions.) For those languages in which other syntactic processes have been described (e.g., relativization, clefting, raising, coreferential deletion, and control of second-position clitics), the following preliminary generalization can be made: in South Philippine languages, control of syntactic processes seems to be more or less evenly distributed between A and O in transitive sentences, but in Sama languages, control for nearly all of these processes (including second-position clitics) is governed exclusively by O in transitive sentences, making the Sama languages highly syntactically ergative languages. As for all Philippine languages, S is always the syntactic control in single-argument sentences.

Mainland Southeast Asia – the Area, Its Languages and Language Families, Its History

Mainland Southeast Asia geographically covers the area of Vietnam, Laos, Cambodia, Thailand, Myanmar, peninsular Malaysia, and southern and southwestern China. This area is characterized by at least two millennia of lively exchange and interaction among speakers of languages that belong to no fewer than five families: Sino-Tibetan, Mon-Khmer (a subfamily of Austroasiatic), Tai (the core group of the Tai-Kadai languages), Hmong-Mien (also called Miao-Yao) and Chamic (Malayo-Polynesian subfamily of Austronesian). The families forming the core of mainland Southeast Asia as a zone of

Table 1 Subgrouping of Mon-Khmer (MK) languages (according to Diffloth & Zide, 1992)

Northern	Khmuic (N Laos/N Thailand)	Khmu, Mal-Phrai, Mlabri
	Palaungic (N Laos/N Thailand, E Burma, SW Yunnan)	Eastern: Riang dialects, Danau Western: Waic, Angkuic, Lametic
	Khasian (NE India)	Khasi
Eastern	Khmeric	Khmer
	Bahnaric (35 languages in Central and S Vietnam, S Laos, E Cambodia)	South: Srê, Mnong, Stieng, Chrau Central: Bahnar, etc. West: Brao (Lave), Nya-heuny (Nyaheun), etc. North: Rengao, Sedang, etc.
	Katuic (Central Vietnam/Laos, NE Thailand, N Cambodia)	West: Kuy, Bru, Sô, etc. East: Katu, Pacoh, Ngeq, etc.
	Pearic (Central Cambodia; affiliation uncertain)	Samrê, Pear, Sa-och (Sa'och), Chong
Viet-Muong (is probably a branch of Eastern MK)		Vietnamese, Muong, etc.
South	Monic	Mon (Myanmar, Thailand), Nyahkur (E Central Thailand)
	Aslian (interior Malaysia, 16 languages)	Senoic: Semai, Temiar; North: Kintaq, Jahai (Jehai), Batek; South: Mah Meri (Besisi), Semelai; Jah Hut
	Nicobarese (Nicobar Islands, may be another direct branch of MK)	Four subgroups

Table 2 Subgrouping of Tai languages (according to Li, 1977; for more information, see Edmondson and Solnit, 1997)

Southwestern	Ahom (Assam/India; extinct) Central Thai (= Siamese) East Central: Black Tai (Tai Dam) (N Vietnam), Red Tai (Tai Daeng) (North Central Vietnam), Phu Tai (Phuan) (Laos/Thailand) Khamti (NW Myanmar; Assam) Lanna (N Thailand): Mueang, Northern Thai, Yuan Lao (Laotian, including Isan in Thailand) Lue (Lü) (called Dai in China; situated in Yunnan) Shan (SE Myanmar, Thailand) Southern Thai White Tai (Tai Dón) (N Vietnam) etc.
Central Tai	Nung (on both sides of the Chinese-Vietnamese border), Southern Zhuang (China, Zhuang Autonomous Region), Tho (= Tay and Caolan; NE Vietnam, S China)
Northern Tai	Bouyei (Buyi), Saek (Central Laos near Vietnamese border, NE Thailand), Northern Zhuang (across S China)

contact-induced convergence are Mon-Khmer, Tai, Hmong-Mien and Sinitic. The Hmong-Mian languages are divided into the Hmong (Miao) and the Mien (Yao) subfamilies. They are spoken in small areas of southern China and in northern Vietnam, Laos, and Thailand. The architecture of the other families is presented in Tables 1–3: Table 1 is on Mon-Khmer, Table 2 on Tai, and Table 3 on Sinitic.

The present linguistic situation in mainland Southeast Asia is the result of extensive migrations, the rise and fall of many kingdoms, and innumerable contact situations (on the historical facts, see Wyatt, 1982). In the first millennium A.D., the inhabitants of this area had contacts with China and India. Vietnam, in the east, was governed by China between 179 B.C. and 938 A.D., while the west and the south were influenced by Theravada Buddhism through the mediation of the Mon (cf. the large corpus of Sanskrit and Pali words in modern Thai and Khmer). The geography of mainland Southeast Asia and its large rivers in particular directed migration from southern China toward Thailand, Laos, and Vietnam. Apart from Chinese and Indian influence, the first millennium A.D. is characterized by the steady emergence of greater political structures. At its end, we find the state of Vietnam, the kingdom of Champa (on the coast of central Vietnam; Austronesian: Chamic), the Khmer empire of Angkor, the kingdoms of central and northern Thailand, and the Burmese kingdoms of Mon and Pyu. At about the same time, numerous speakers of Tai languages migrated from inland southern China (Guizhou, Guangxi) to the south and changed the balance in the north towards the Tai population, which simultaneously became an important reservoir of manpower and a potentially dangerous rival for the adjacent kingdoms. Cambodia moved its center of gravity from Angkor further south to Phnom Penh, and the newly developed Thai kingdoms of Sukhothai (?1240–1438) and Ayudhya (1351–1767) were characterized by intensive contact and presumably by a considerable proportion of bilinguals. As a consequence, there is a high degree of structural similarity and some lexical similarity between the two languages. Finally, the migration of a considerable number of Hmong-Mien from southern and southwestern China to Laos, Vietnam, and Thailand started in the middle of the 19th century.

Table 3 List of Sinitic languages/dialects (Chappell, 2001: 6)

Northern Chinese (N China, W China, par of central China, Sichuan basin, Guizhou and Yunnan provinces)
Xiāng (Xiang Chinese) (Hunan province)
Gàn (Gan Chinese) (Jiangxi province)
Wú (Wu Chinese) (coastal area of lower Yangze River in the provinces of Jiangsu, Zhejiang and Anhui)
Mǐn (Min Nan Chinese) (Southern coastal province of Fujian and the island of Taiwan, Leizhou peninsula plus Hainan island)
Kèjiā or Hakka (Hakka Chinese) (scattered throughout SE China in small communities in the Yuè and Mǐn areas)
Yuè (Yue Chinese) (Guangdong and Guangxi provinces; Cantonese)
Recently identified dialect groups:
Jìn (Jinyu Chinese) (Shanxi province and Inner Mongolia)
Pínghuà (Guangxi)
Huī (Huizhoun Chinese) (in parts of Anhui, Jiangxi and Zhejiang provinces)

Given the long-lasting and very complex patterns of interaction among speakers of a large number of languages from different families, structural convergence comes as no surprise. Studies dealing with mainland Southeast Asia from an areal perspective are Huffman (1973), Clark (1978), Capell (1979), Clark (1989), Matisoff (1991), Bisang (1992), Bisang (1996), and Enfield (2003). Huffman (1986) is an excellent bibliography on the languages and linguistics of this area.

General Properties of the Languages of Mainland Southeast Asia – the Relevance of Pragmatics

Mainland Southeast Asian languages are characterized by a high degree of indeterminateness, which as a consequence endorses the relevance of pragmatic inferencing and produces a special type of pragmatics-oriented grammaticalization (see 'Indeterminateness and the Role of Pragmatics' below). The pragmatics-oriented character of grammaticalization may be one reason for a syllable-based morphology (see 'Syllabic Morphology' below). Another consequence of this type of grammaticalization may be the comparatively weak correlation between the lexicon and individual lexical items (see 'Versatility' below).

The above pragmatics-based properties will be discussed in this section. Two additional general properties will be treated in the subsection 'Directional Verbs, Coverbs and TAM Markers, and Syntactic Patterns' with the necessary language-specific details. The properties are the existence of rigid syntactic patterns with fixed functionally determined positions and the functional motivations of these patterns.

Table 4 Some nonobligatory categories in mainland SE Asian languages

Verb	*Noun*
Person/Number	Number
Tense/Aspect/Modality (TAM)	Noun class
Transitivity (transitive vs. intransitive)	Reference (definite, specific, indefinite)
Diathesis	Relationality (possession)
Causativity	Case

Indeterminateness and the Role of Pragmatics

East and mainland Southeast Asian languages are well known for their indeterminateness, i.e., their lack of obligatory categories (Bisang, 1992, 2001, see also context dependency in Enfield, 2003: 55). One famous instance is the lack of obligatory arguments. In the following example from Modern Standard Chinese (Mandarin Chinese), the agent argument *wǒ* 'I' and the patient argument *tā* 'he' are no longer mentioned in the second clause with the predicate *jiàn* 'see' because they are already known from the previous context.

(1) wǒ$_1$ bú jiàn tā$_2$ yǐ shì sān
I *NEG* *see* *he* *already* *be* *30*
shíduō nián; jīntiān ø$_1$ jiàn ø$_2$ le
more *year* *today* *see* *PF*
'I haven't seen him for more than 30 years. Today [**I**] saw [**him**]'
(from Lu Xun, *Kuangren riji* [*Diary of a Madman*], second sentence).

Dropping arguments (prodrop) is not the only instance of indeterminateness. There are also a large number of grammatical categories which are optional (cf. Table 4), i.e., the speaker is not committed to select a particular subcategory (e.g., past, present, or future) from a particular obligatory category (e.g., tense).

Indeterminateness implies that grammatical categories which are expressed obligatorily in other languages must often be inferred from the context in mainland Southeast Asian languages. If these categories are expressed, however, they are very often expressed by lexical items which occur in a special syntactic position of a construction where they get reanalyzed as grammatical markers. This type of grammaticalization differs from grammaticalization as described in the literature by dint of the vast functional range of many markers (see 'Classifiers' and "The Verb 'Come to Have'" below) and the lack of a form–meaning correspondence (see 'Directional Verbs, Coverbs and TAM Markers, and Syntactic Patterns'). The mainland Southeast Asian languages show that a high degree of abstraction (semantic

generality, cf. Bybee, 1985) does not automatically lead to morphological reduction (see 'Syllabic Morphology' below); in other words, the semantic integrity of a linguistic sign is not fully reflected in its phonological integrity (Lehmann, 1995). The high functional range of individual markers is sometimes observed within an individual language, sometimes across languages. In the latter case, individual languages select certain domains out of the whole inferential potential of a marker common to a wider contact zone (see 'Directional Verbs, Coverbs and TAM Markers, and Syntactic Patterns' on verbs with the meaning 'finish' and the end of "The Verb 'Come to Have'").

The high relevance of pragmatics led to a more general discussion of the relevance of syntax in mainland Southeast Asian languages. Diller (1988) talked about "pragmatically organised syntax" in the context of Thai and other languages. Huang (1994) argued, against Huang (1984), that the interaction of syntax and pragmatics is subject to typological variance:

> There seems to exist a class of language (such as Chinese, Japanese, and Korean) where pragmatics appears to play a central role which in familiar European languages (such as English, French, and German) is alleged to be played by grammar. In these 'pragmatic' languages ... (Huang, 1994: xiv)

Syllabic Morphology

Mainland Southeast Asian languages are characterized by or drift towards a morphology whose smallest meaningful element is the syllable. This definition encompasses the well-known monosyllabism of languages such as Chinese (Mandarin Chinese) or Vietnamese (each syllable has its own meaning) but it also covers such cases as Thai or Khmer, which easily accept strings of semantically unanalyzable syllables, as in the elegant word for 'restaurant' in Thai (*pháttaakhaan*) or in Khmer (*phòːcənìːəṭṭhaːn*).

This does not mean that subsyllabic morphology does not exist in mainland Southeast Asia, but the integration into that area seems to engender a drift towards syllabic morphology. This can be illustrated by Mon-Khmer. Vietnamese, which was under the strong influence of monosyllabic Chinese for more than a millennium (see above), has completely lost its subsyllabic morphology, while Khmer, which had weaker contacts with China and was even able to transfer a lot of its vocabulary to Thai, probably has the richest morphology within the Mon-Khmer family (on Khmer morphology see Jenner and Pou, 1980–1981; Haiman, 1998). In spite of this, Khmer morphology is basically a lexical phenomenon, i.e., the affixes are not used productively. The productive strategies are all based on products of grammaticalization (as described in the subsections 'Classifiers,' 'Directional Verbs, Coverbs and TAM Markers, and Syntactic Patterns,' and "The Verb 'Come to Have'"). In addition, Khmer subsyllabic morphology is characterized by the following two properties: (1) a large number of Khmer affixes lack functional consistency, i.e., the same marker can express different functions depending on its base (the prefix *prə-* marks causativity/factivity, change of word class and reciprocity); and (2) the same function can be expressed by different affixes (e.g., derivation of nouns from verbs belongs to the functional range of the following affixes: *k-*, *s-*, *m-*, *N-*, *bvN-*, *kvN-*, *svN-*, *-b-*, *-m-*, *-n-*, *-vmn-/-vN-*) (Bisang, 2001: 195–200).

Versatility

The term 'versatility' refers to the fact that the occurrence of a given linguistic item is not limited to a single syntactic position (Matisoff, 1969). A word's freedom to occur in the N-position as well as in the V-position is one instance of versatility. In the extreme case of Late Archaic Chinese (5th–3rd century BC), any lexical item can take the verbal position, even a proper name:

(2) Late Archaic Chinese (Zuo, Ding 10)
Gōng Ruò yuē: ěr **Wú wáng** wǒ hū?
Gong Ruo say you Wu king I Q
'Gong Ruo said: "Do you want to deal with me as **King Wu** was dealt with?"'
(King Wu was murdered. → "Do you want to **kill** me?")

Versatility may also enhance grammaticalization in the sense that full lexemes can take positions associated with grammatical functions. As is typical of versatility, one lexical item can take different functions depending on the construction in which it is used. Thus, the verb *ʔaoy* 'give' in Khmer can occur as a coverb (3), as a causative verb (4), or as an adverbial subordinator (5). The same applies to Vietnamese *cho* 'give' and to Thai *hây* 'give' (cf. Bisang, 1996: 577–578).

(3) kɔ̀ət baək tvìːə(r) **ʔaoy** khɲom
he open door give.COVERB I
'he opens the door for me'

(4) mdaːy-mìːŋ sovaṇ(ṇ) **ʔaoy** svaːmɤy cùːn
aunt Sovan give.CAUS husband give a lift
phɲiəv tɤ̀u phtɛ̀əh
guest Vd:go house/home
'Aunt Sovan had her husband bring the guests back home' (Bisang, 1992: 440)

(5) khɲom khɔm thvə̀:-ka:(r) ʔaoy
I *try* *hard work* *so that.*COMP
ʔo:pùk khɲom sɔpba:y-cʋt(t)
father *I* *be-pleased*
'I am working hard so that my father will be pleased.'

The versatility of lexical items may turn out to be another consequence of the high relevance of pragmatics in the sense that the positioning of lexical items into syntax is governed to a lesser or to a greater degree by pragmatics.

Some Individual Structural Properties of the Languages of Mainland Southeast Asia

This section will mostly refer to one or more of the following languages: Chinese (Mandarin Chinese) (Sinitic), White Hmong (Hmong Daw) (Hmong-Mien), Vietnamese (Mon-Khmer), Thai (Tai) and Khmer (Mon-Khmer). Apart from word order; classifiers; directional verbs (Vd), coverbs (COV), and TAM markers derived from verbs; and different functions of the verb 'come to have,' there are other characteristics of mainland Southeast Asia as a zone of convergence which will not be discussed here. I would like to refer to relational nouns (nouns such as Thai *nâa* 'front' in adpositional function with the meaning 'in front of'), causatives marked by the verbs 'make, do' and 'give, allow' in Vietnamese, Thai, and Khmer (Bisang, 1992: 42–44; see also example (4) above), passivelike constructions with a tendency to adversative meaning, complementizers and adverbial subordinators derived from verbs such as 'say,' 'give' (cf. example (5) above), 'finish' and others, and, finally, comparative constructions based on verbs with the meaning 'surpass' (e.g., in Cantonese, Thai, Vietnamese).

Word Order

The large majority of the languages belonging to the mainland Southeast Asian convergence zone are VO (verb middle, including Chinese [Mandarin Chinese]). The noun phrase is subject to variance. While Chinese (Mandarin Chinese) is consistently head final, Thai and Khmer are consistently head initial. Hmong and Vietnamese are head initial with the exception of the classifier phrase, which follows the Chinese (Mandarin Chinese) example. There are prepositions (coverbs) in all the languages; Chinese also has postpositions (relational nouns, i.e., nouns in adpositional function). Since numerals covary with classifiers, there is no extra column for them in Table 5.

Classifiers

Classifiers are minimally used with numerals, where their presence is overwhelmingly compulsory in mainland Southeast Asian languages. Thus, a Chinese (Mandarin Chinese) noun like *xìn* 'letter' must take a classifier (*fēng*) if it is counted:

(6) sān fēng xìn
three CLASS *letter*
'three letters'

There is an implicational correlation between the existence of a classifier and the lack of obligatory number distinction (transnumerality): "Numeral classifier languages generally do not have compulsory expression of nominal plurality, but at most facultative expression" (Greenberg, 1974: 25). Since nouns in mainland Southeast Asian languages only denote a concept without any commitment to number, one of the functions of the classifier is to make that concept accessible by individuating it, i.e., by highlighting one of its conceptual boundaries which qualify it as a unit (Bisang, 1999). The semantic criteria for highlighting a concept also classify that concept. Typical criteria for classification are material (animate, abstract, inanimate), shape (one-/two-/three-dimensional), consistency (flexible, hard or rigid, discrete), size (big, small), location (classifiers for plots of land, countries, gardens, fields, etc.) and spatial arrangement (Allan, 1977). Other criteria are based on physical, functional, and social interaction with the concept to be classified (Denny, 1976).

Classification can not only be used to individuate a concept by highlighting some of its properties; it can also be used for identifying one or more relevant objects denoted by a concept. While identification can take place without referring to individuation – one can identify an 'apple' without referring to its conceptual boundaries – it seems difficult to individuate it without simultaneously identifying it.

Table 5 Word order in mainland southeast Asia

	Verb/Object	*Adposition*	*Demonstrative*	*Classifier*	*Possessor/Genitive*	*Relative Clause*
Chinese	VO	Prep/Postp	DemN	CIN	GenN	RelN
Hmong	VO	Prep	NDem	CIN	NGen	NRel
Vietnamese	VO	Prep	NDem	CIN	NGen	NRel
Thai	VO	Prep	NDem	NCl	NGen	NRel
Khmer	VO	Prep	NDem	NCl	NGen	NRel

Departing from classification, one can thus establish the following hierarchy:

(7) classification > identification > individuation

Identification can be used either to mark the definiteness or specificity of a concept (referentialization) or to make it accessible for construction with for example a possessor or a relative clause (relationalization).

Taking together the functional range of classifiers in mainland Southeast Asia, there are no fewer than four functions: classification, individuation, referentialization, and relationalization. These functions are not equally distributed across Southeast Asia. The minimal functions operating in all the languages are classification and identification. Table 6 provides a survey (Bisang, 1999).

The following examples from Hmong illustrate the functions of classification/individuation (8a) and of relationalization (possession) (8b).

(8a)	peb	rab	riam
	three	CLASS	*knife*
	'three knives'		
(8b)	nws	rab	riam
	he	CLASS	*knife*
	'his knife'		

The referential function of classifiers is more difficult to show because this needs a lot of text. Once a concept is introduced, it can be marked as definite, sometimes by the classifier alone, sometimes by classifier plus demonstrative, sometimes only by the demonstrative (for more, see Bisang, 1999: 152–153). It is, however, necessary to point out that reference marking is not compulsory. Thus, an unmarked noun can get any possible referential interpretation depending on context.

Directional Verbs, Coverbs and TAM Markers, and Syntactic Patterns

Markers derived from lexical items used for expressing directionality, adpositional functions, and tense-aspect-modality (TAM) are widespread in mainland Southeast Asia.

The direction taken by a state of affairs can be overtly expressed with directional verbs (Vd). Verbs belonging to this category have the meanings of 'come,' 'go,' 'move upwards,' 'move downwards,' 'move into,' and 'move out of.' In Khmer, there is a maximum of three slots (9), while Thai has only two slots and Vietnamese only one.

(9)	kɔ̀ət	yɔ̀ːk	ʔʏyvan **coh**
	he	*take*	luggage *move. down*.DIR
	cën	**mɔ̀ːk.**	
	move. out.DIR	*come*.DIR	
	'He takes [his] luggage down and out [of his room upstairs towards the speaker]'		

Verbal lexemes in adpositional function are called coverbs (COV) (see Clark, 1978). An instance of the verb 'give' in that function is discussed in the subsection 'Versatility.' Other frequently used verbs are 'be at' (locatives or directionals), 'arrive' (directionals), 'move along something' (path), 'use' (instrumental), 'be equal to' (work as, do something in the function of), and 'replace' (instead of). The following example is from Vietnamese:

(10)	tôi	làm	việc	**ở**	Sài gòn.
	I	*do*	*work*	*be.at*.COV	*Saigon*
	'I work in Saigon'				

Verbs in the function of TAM markers can occur in the preverbal position or clause finally (in Chinese [Mandarin Chinese], there are also the three TAM markers *-le*, *-zhe* and *-guo*, which are suffixed to the verb). The verb 'finish' in clause-final position, which is very widespread, is briefly looked at in this subsection (see also the next subsection on 'come to have'). In Chinese (Mandarin Chinese), the clause-final marker *le* (derived from *liǎo* 'finish') marks a wide range of functions from perfect to the pragmatic function of reference to a preconstructed domain (Li *et al.*, 1982; Bisang and Sonaiya, 1997). Thai *lɛ́ɛw*, which is borrowed from Chinese *liǎo* 'finish,' is an aspectual marker highlighting event-initial or event-final temporal boundaries. The functions of Hmong *lawm* (again related to Chinese *liǎo*) or *tas (lawm)* 'finish,' Vietnamese *rồi* 'finish,' and Khmer *haəy* (nowadays only used as a TAM marker, but cf. its transitive form *bɔŋhaəy* 'finish') cover the same functional range as *le* and *lɛ́ɛw*. Unfortunately, there is no detailed comparative analysis available.

If directional verbs, coverbs, and TAM markers are part of the same state of affairs, they follow a fixed pattern of word order (cf. serial unit in Bisang, 2001) described in Table 7 and illustrated by example (11) from Khmer.

Table 6 Functions of classifiers in individual languages

I. *Classification & individualization*
Modern Standard Chinese (Mandarin Chinese) (classifiers with numerals and demonstratives)
Vietnamese (individualization, but not necessarily in the context of counting)
II. *Classification & individualization & referentialization*
Thai (secondary function in combination with stative verbs in N-CLASS-ADJ)
III. *Classification & individualization & relationalization*
Cantonese (yue Chinese) (classifiers can be used in possessive and relative constructions)
IV. *Classification & individualization & referentialization &* relationalization
Hmong (with referentialization being a secondary function)

(11) kɔ̀ət **ba:n** yɔ̀:k ʔʏyvan **coh**
the be.able.TAM take luggage move.down.DIR
cëŋ **mɔ̀:k.** **ʔaoy** khɲom.
move.out.DIR come. DIR give.COV I
'he was able to bring [his] luggage down and out [of his room upstairs towards the speaker] to/for me.'

As can be seen from Table 7, the structure of the serial unit follows a certain areal clustering. Vietnamese, Thai, and Khmer, in the south, follow exactly the same pattern. Chinese (Mandarin Chinese), in the north, differs with regard to the following three properties: preverbal coverbs, TAM markers immediately after the verb and COV–Vd word order. Hmong lies in between. It shares the former two word order properties with Chinese (Mandarin Chinese) and the last property with the southern languages.

The above word order is not arbitrary even if one looks at languages spoken outside mainland Southeast Asia with comparable structures (Bisang, 2001: 202–214). It can be accounted for in terms of semantic generality as introduced by Bybee (1985). Increasing semantic generality of a marker is related to compatibility with more lexical stems and to greater morphosyntactic fusion with the stem. Thus, maximally general grammatical categories are prototypically expressed inflectionally. Although there is no iconic correlation between the degree of semantic abstraction and morphological attrition in mainland Southeast Asia (see 'Syllabic Morphology' above), there is a form–meaning iconicity if one looks at the relative distance of the markers to the main verb. The further away a marker is from the main verb the more general it is. Directional verbs and coverbs still have enough semantic weight to be incompatible with many verbs. This is not the case with the semantically more general TAM markers. Therefore, TAM markers are situated at a greater distance from the verb than coverbs and directional verbs. Coverbs and directional verbs seem to share about the same degree of generality. Consequently, we find COV-Vd as well as Vd-COV.

The Verb 'Come to Have'

There is an excellent study on the grammaticalization of the verb 'get, come to have' from an areal perspective in mainland Southeast Asia in Enfield (2003). Verbs such as Chinese (Mandarin Chinese) *dé*, Hmong *tau*, Vietnamese *được*, Thai *dây*, or Khmer *ba:n* with that meaning induce a large number of different inferences depending on the context. Enfield (2003) translates these verbs with 'come to have.' This translation is more adequate than the one with 'get' because it does not imply an agentive subject.

Although 'come to have' verbs occur preverbally as well as postverbally, a look in this subsection at their preverbal functions will be enough to illustrate the rich inferential potential. Their basic meaning in this position is that the state of affaires expressed by the main verb is true or applies "because of something else that happened before this" (Enfield, 2003: 292). A set of inferences depends on whether the state of affairs denoted by the verb is understood as [+wanted] or [−wanted]. If it is wanted, we get either an abilitative (be able) or a permissive (be allowed) inference (12); if it is not wanted, we get a strong deontic (must, have to) interpretation (13).

(12) Hmong (Mottin, 1980; Bisang, 1992: 241):
koj mus deev hluar nkauj,
you go court girl
koj puas **tau** nrog tham?
you Q PFV with.COV talk
'you courted the girl, did you [manage to] talk to her?'

(13) Chinese (Mandarin Chinese) (in its deontic function, *dé* 'get' becomes *děi*):
tā **děi** xuéxi zhōngwén.
s/he must learn Chinese
'S/he must learn Chinese'

Many grammarians of individual languages describe 'come to have' verbs as past markers. In spite of this, past is only another possible inference, but not a clear-cut grammatical category. The following Khmer example from Enfield (2003: 314) can also trigger other temporal inferences in other contexts:

(14) khɲom **ba:n** rìəp-ka:(r)
I get.TAM marry
ta:m prəpèynì: khmae(r)
according.to.COV custom Khmer
'I married according to Khmer custom'
(could mean in other contexts 'I would/will get to/have to marry . . .')

A fourth inference, treated only marginally by Enfield (2003), is emphasis of the truth. This

Table 7 Positions within the serial unit

Chinese	TAM	COV	V-TAM	COV	Vd	TAM
Hmong	TAM	COV	V TAM	Vd	COV	TAM
Vietnamese	TAM		V	Vd	COV	TAM
Thai	TAM		V	Vd	COV	TAM
Khmer	TAM		V	Vd	COV	TAM

inference is related to the fact that for the agent to be able to 'come to have' a given state of affairs, that state of affairs needs to be true.

(15) Hmong (Mottin, 1980: 94):

saib	yog	leej	twg	**tau**
look	*be*	*man*/CL	*which*	PFV
ua	txhaum	zoo li cas	lawm?	
make	*mistake*	*like.this*	PERF	

'[we want to] see who [really] made such a mistake'

In spite of their rich inferential potential, most languages show preferred inferences or even completely exclude certain inferences. Thus, the meaning of preverbal 'come to have' in Chinese (Mandarin Chinese) is conventionalized into deontic modality. Vietnamese prefers the abilitative or permissive interpretation but is compatible with a must-interpretation. Thai and Khmer are more open, with a functional core of abilitative/permissive and past. Hmong shows a certain preference for past (Enfield, 2003: 319) but certainly does not exclude abilitative/permissive inferences.

Conclusion – Factors Leading to a Zone of Convergence

Mainland Southeast Asia is characterized by a special type of pragmatics-oriented grammaticalization and by a number of shared products of grammaticalization and syntactic patterns. The structural convergence observed in this zone is the result of a very complex interaction of cognitive (semantic and pragmatic) factors with social mechanisms of diffusion extended over a large number of different individual situations of contact. Language-internal cognition-based processes of change are combined with and sometimes enhanced or interrupted by contact-induced changes. When it comes to social factors, any of the social models accounting for the cross-linguistic diffusion of structural properties presented in the literature can contribute their part. Thus, the diffusional pattern of the properties relevant for mainland Southeast Asia as a zone of convergence is most likely a joint product of social networks, leaders of linguistic change, and invisible-hand processes (*see* **Contact-Induced Convergence: Typology and Areality** for more information on these social mechanisms).

Southern Bantu Languages

L Marten, School of Oriental and African Studies, London, UK

© 2006 Elsevier Ltd. All rights reserved.

Introduction

Southern Bantu languages include Bantu languages spoken in South Africa, Swaziland, Lesotho, Botswana, Zimbabwe, and southern Mozambique. The term 'southern Bantu languages' is usually taken to refer to the geographical-referential classification, and hence as not implying genetic relations, of the following languages and language groups: the Nguni group (including Zulu, Xhosa, Swati, Ndebele), the Sotho-Tswana group (including Northern Sotho, Sesotho [Sotho, Southern], Tswana), the Tswa-Ronga group, the Imhambane group, and also Shona and Venda. The Bantu languages of Angola and Namibia, such as Herero or Wambo, are usually not included under southern Bantu, but are referred to as southwestern Bantu. In terms of Guthrie's (1967–1971) classification, southern Bantu languages are grouped as zone S. The designation 'southern Bantu languages' was re-enforced by Doke's monograph with the same title published in 1954.

Historically, the southern Bantu languages provide the endpoint of the so-called Bantu expansion, a period of migration and contact of more than 2000 years, during which Bantu languages slowly came to be spoken throughout the larger part of sub-Saharan Africa. The origin of the Bantu expansion lies in the Nigeria-Cameroon borderland, and the direction of the expansion was hence southwards and ended with Bantu languages reaching the southern African coastline about 1,500 years ago, coming from eastern and central Africa. Speakers of southern Bantu languages have probably shared an extended, and extensive, period of contact with speakers of Khoisan languages present in southern Africa when Bantu languages arrived. The differentiation of distinct Bantu languages, and the establishment of standardized forms occurred more recently. From the 19th century onwards, written literature was produced in the larger southern Bantu languages, and several are among the dominant languages in the countries where they are spoken. For example, all nine Bantu languages of the national languages of the Republic of South Africa (in other words, all national languages except for English and Afrikaans) are southern Bantu languages.

Southern Bantu languages have played an important part in the history of Bantu studies. While the earliest descriptions of Bantu languages are from west-central and eastern Africa, scholarship in southern African Bantu languages provided the impetus for a number of early comparative Bantu studies

Southern Bantu Languages

L Marten, School of Oriental and African Studies, London, UK

Introduction

Southern Bantu languages include Bantu languages spoken in South Africa, Swaziland, Lesotho, Botswana, Zimbabwe, and southern Mozambique. The term 'southern Bantu languages' is usually taken to refer to the geographical-referential classification, and hence as not implying genetic relations, of the following languages and language groups: the Nguni group (including Zulu, Xhosa, Swati, Ndebele), the Sotho-Tswana group (including Northern Sotho, Sesotho [Sotho, Southern], Tswana), the Tswa-Ronga group, the Imhambane group, and also Shona and Venda. The Bantu languages of Angola and Namibia, such as Herero or Wambo, are usually not included under southern Bantu, but are referred to as southwestern Bantu. In terms of Guthrie's (1967–1971) classification, southern Bantu languages are grouped as zone S. The designation 'southern Bantu languages' was re-enforced by Doke's monograph with the same title published in 1954.

Historically, the southern Bantu languages provide the endpoint of the so-called Bantu expansion, a period of migration and contact of more than 2000 years, during which Bantu languages slowly came to be spoken throughout the larger part of sub-Saharan Africa. The origin of the Bantu expansion lies in the Nigeria-Cameroon borderland, and the direction of the expansion was hence southwards and ended with Bantu languages reaching the southern African coastline about 1,500 years ago, coming from eastern and central Africa. Speakers of southern Bantu languages have probably shared an extended, and extensive, period of contact with speakers of Khoisan languages present in southern Africa when Bantu languages arrived. The differentiation of distinct Bantu languages, and the establishment of standardized forms occurred more recently. From the 19th century onwards, written literature was produced in the larger southern Bantu languages, and several are among the dominant languages in the countries where they are spoken. For example, all nine Bantu languages of the national languages of the Republic of South Africa (in other words, all national languages except for English and Afrikaans) are southern Bantu languages.

Southern Bantu languages have played an important part in the history of Bantu studies. While the earliest descriptions of Bantu languages are from west-central and eastern Africa, scholarship in southern African Bantu languages provided the impetus for a number of early comparative Bantu studies

(Lichtenstein, 1808; Bleek, 1862, 1869; Torrend, 1891). Bleek (1862) is credited with coining the term 'Bantu' based on the plural form for 'people' in Xhosa and in many other Bantu languages. In the 20th century, a major figure in the study of southern Bantu languages was Clement Doke, who produced numerous grammatical descriptions of southern Bantu languages and also proposed an analytical system for the description of Bantu languages, which became particularly influential in South Africa (Doke, 1935). Due to the official status of nine southern Bantu languages in South Africa and an increase in institutions of tertiary education, there is currently a wealth of new linguistic scholarship in southern Bantu languages, often with particular emphasis on lexicography, computational linguistics, and applied linguistic topics such as language policy and language teaching. Most of the southern Bantu languages with large numbers of speakers (Zulu, Xhosa, Northern Sotho, Sesotho, Tswana) have, often recent, comprehensive reference grammars and dictionaries, as well as a range of teaching materials for schools and independent learners.

Classification

The southern Bantu languages are, following Guthrie (1967–1971), classified into six groups within zone S (cf. Gowlett, 2003).

The Shona group (S10) comprises six clusters: Korekore, Zezuru, Manyika, Karanga, Ndau, and Kalanga. A standardized form of Shona based on the Korekore, Zezuru, and Karanga varieties is used as an official language in Zimbabwe. In addition to Zimbabwe, languages of the Shona group are also spoken in parts of Mozambique and Botswana (Kalanga). There are close to 9 million speakers of Shona.

The Venda group (S20) only includes Venda, spoken by around 800 000 speakers in South Africa's Northern Province and adjacent southern Zimbabwe. Venda is an official language of South Africa.

The Sotho-Tswana group (S30) includes Tswana, Northern Sotho, and Southern Sotho, all of which are cover terms for a number of related varieties. Sometimes also Lozi, spoken in western Zambia and Namibia's Caprivi strip, is classified as a Sotho-Tswana language. Standard forms of these languages are based on a majority variety, and smaller varieties are often threatened with marginalization. Tswana is an official language in Botswana and South Africa, with about 4 million speakers. Northern Sotho, also Sesotho sa Leboa, is spoken in the northeast of South Africa by about 3.6 million speakers and is an official language of South Africa. Southern Sotho, or Sesotho, with more than 4 million speakers, is spoken in Lesotho and South Africa and it is an official language in both countries.

The Nguni group (S40) is divided into Zunda varieties and Tekela varieties. Among the Zunda varieties are Xhosa, Zulu, and Zimbabwean Ndebele. Xhosa includes a number of different varieties. Zulu, with around 10.7 million speakers, and Xhosa, with around 7.2 million speakers, are official languages of South Africa. Zimbabwean Ndebele has official status in Zimbabwe. The Tekela varieties include Swati, South African Ndebele, and the smaller languages Phuthi and Lala (Lala-Bisa). Swati has around 1.6 million speakers and is an official language both in Swaziland and South Africa. The southern variety of South African Ndebele is an official language in South Africa, spoken by around 0.6 million speakers.

The Tshwa-Ronga group (S50) includes Tshwa, Tsonga, and Ronga, all of which are spoken in Mozambique. Tshwa, with 0.7 million speakers, is also spoken in Zimbabwe, and Tsonga, with more than 3 million speakers, is also spoken in South Africa, where it is an official language.

The Inhambane, or Copi, group (S60) includes two languages spoken in the Inhamabane area of Mozambique: Copi (Chopi), with around 0.5 million speakers, and GiTonga, with around 0.3 million speakers.

Structural Features

Phonologically, southern Bantu languages are characterized by symmetric five (e.g., Nguni) or nine (e.g., Sotho) vowel systems, two tonal distinctions (high vs. low), and complex consonant systems, often including a three-way distinction between voiceless-aspirated, voiceless-unaspirated, and voiced stops and affricates, as well as several series of prenasalized consonants. A number of southern Bantu languages have borrowed click consonants from Khoisan languages during an extended period of contact, e.g., Xhosa, which has dental [ǀ], alveolar [!] and lateral [ǁ] clicks (written as *c*, *q*, and *x*). A comparatively untypical Bantu feature of southern Bantu languages are depressor consonants, an often phonologically heterogeneous group of consonants that cause a following high tone to lower, as in the Zulu example below, where the depressor consonant /z̪/ in the plural prefix causes the following high tone to shift to the following syllable, resulting in a different tone pattern:

Table 1 Noun class prefixes in southern Bantu languages

Class	*Shona*	*Venda*	*Sesotho*	*Zulu*	*Tsonga*	*Copi*
1	mu-	mu-	mo-	um(u)-	mu-	in-
2	va-	vha-	ba-	aba-	va-	va-
3	mu-	mu-	mo-	um(u)-	mu-	in-
4	mi-	mi-	me-	imi-	mi-	mi-
5	Ø-	ḷi-	le-	i(li)-	ri-	di-

21	zi-	ḍi-	-	-	ji-	-

(1) *ìsíhlàlò* 'chair' *ìẓìhlâlò* 'chairs'

Morphologically, southern Bantu languages, like the majority of Bantu languages, are characterized by their noun classes, and the agreement, or concord, system built on it, as well as by complex verbal morphology. Nouns are grouped into 15 to 20 noun classes that are morphologically marked by a noun class prefix, usually of CV shape and sometimes accompanied by a pre-prefix vowel (see Table 1).

The noun class of the head noun triggers class agreement of dependent nominals, as well as subject and object concord (agreement) morphology in the inflected verb. The term agreement, although well established, can be misleading, as subject and object markers can function as subject and object, and no overt lexical NP is needed for a well-formed sentence, as the following Zulu example (from Poulos and Bosch, 1997) shows:

(2) ngi-zo-ba-sebenz-el-a
SM1sg-FUT-OM2-*work*-APPL-FIN
'I will work for them'

In addition to subject and object markers, inflected verbs can show morphological marking of negation, tense, aspect and mood, typically prefixed to the verbal base. The verbal base consists of a root that may be suffixed by several derivational suffixes (so-called extensions), such as applicative, causative, stative, reciprocal, or passive. The following examples from Tswana show how causative and applicative extensions can be used to increase the number of nominal complements of the verb (adapted from Creissels, 2004):

(3a) ng-wàná ó nó-lé má-šì
NP1-*child* SM1 *drink*-PERF NP6-*milk*
'the child drank milk'

(3b) kè nó-s-ítsé ng-wàná má-šì
SM1sg. *drink*-CAUS-PERF NP1-*child* NP6-*milk*
'I made the child drink milk'

(3c) kè nó-s-éd-ítsé Dimpho ng-wàná má-šì
SM1sg. *drink*-CAUS-APPL-PERF *Dimpho* NP1-*child* NP6-*milk*
'I made the child drink milk in Dimpho's place'

A number of morphological features found in southern Bantu languages are not, or only rarely, found in other Bantu languages. In the domain of nominal morphology, these include the use of derivational suffixes for diminutives and feminines (e.g., in Zulu *-ana* and *-kazi*: *indoda*, 'man' and *indodana*, 'son'; *imbuzi* 'goat' and *imbuzikazi*, 'she-goat'), and the replacement of the locative classes by a locative prefix *e-*, a locative suffix *-(i)ni*, or a combination of both. Within verbal inflection, several southern Bantu languages show a distinction between so-called conjoint and disjoint verb forms (sometimes also called definite/indefinite or long/short forms) (Creissels, 1996); for example, in Zulu, verbs in the perfect tense may end in *-e* (short) or *-ile* (long) (Doke, 1963: 335):

(4a) si-bon-e abantu
SM1pl-*see*-PERF *people*
'we saw people'

(4b) si-ba-bon-ile abantu
SM1pl-OM2-*see*-PERF *people*
'we saw (them) the people'

The difference in use of the two forms depends on different factors, among them whether the verb is final in the verb phrase, as in (4b), where the object marker functions as the object of the verb, and the overt NP *abantu* following the verb is hence not part of the VP.

In terms of syntax, southern Bantu languages, like most Bantu languages, have unmarked SVO order (see the examples in (3), above), but, especially in interaction with subject and object markers, the word order is syntactically comparatively free, and rather more constrained by information structure considerations. As an illustration of this, the following Xhosa examples show unmarked subject-verb

order (5) and inverted verb-subject order (6) used to focus the subject *ábántwánà*, 'children', either existentially like in this example, or contrastively, as in (7). Note that the subject marker in (6) and (7) is of the locative class 17 and thus does not show agreement with the subject (Du Plessis and Visser, 1992: 130–131):

(5) ábá-ntwánà bá-yà-ngénà
NP2-*children* SM2-ya-*enter*
'the children enter'

(6) kù-ngénà ábá-ntwánà
NP2-*children* SM2-ya-*enter*
'there enter children'

(7) kù-sèbénzà ámá-dódà, háyi ábá-fázì
SM17-*work* NP6-*men* *not* NP2-*women*
'there are men working, not women'

Although the major southern Bantu languages, those with large numbers of speakers and official status, are comparatively well-described, for a number of smaller southern Bantu languages, some of which are endangered, very little information exists, and descriptive studies are urgently needed. In a wider perspective, the contribution southern Bantu languages can make to general and theoretical linguistic studies has only begun to be fully addressed, and remains to be developed in all areas of linguistic research in the future.

Space: Semiotics

P Pellegrino, University of Geneva, Geneva, Switzerland

© 2006 Elsevier Ltd. All rights reserved.

In a commonly accepted definition coming from Peirce (1867) and quoted in Umberto Eco (1973), a sign is something that, for someone, takes the place of some other thing under some report or to some title. The sign takes the place of the object (Peirce, 1867). The question here is, therefore, how can space make a sign, to substitute for an object?

By extent we mean **that which has a length, a breadth and a depth, without inquiring whether it is a real body or only a space** (Descartes, 1628). For Leibniz, absolute space is the "pure *extensum*," that which possesses all magnitude and no situation (Leibniz, 1679). According to Newton, space is **absolute** or **relative**, **passive** or **active**. Relative (active) space (the interval) takes a place in the absolute (passive) space (unrelated to anything external); it is a **mobile dimension or measure of absolute spaces** (Newton, 1687). As finitude (magnitude) takes place in infinitude (beyond the measure, open process), the limited (the closed line, the limit between an interior and an exterior) carves in the unlimited (beyond the line, open surrounding). But, according to Kant, space is not a thing or a substance, but an ***a priori* form**; it allows us to know our external reality. In space we represent to ourselves the objects on which we act; **that is where we determine their shape, their magnitude and the relationships between them** (Kant, 1781).

The possibility that a space substitutes for an object comes therefore from the fact that it is the prerequisite for the exteriority, simultaneity and juxtaposition of the objects; the prerequisite for their relation, coexistence and integration. And this prerequisite implements not only the opposition of the material and the immaterial, but also that of the continuous and the discontinuous, the homogeneous and the heterogeneous, the here and the elsewhere.

Thus, if the sign affords one object in the place of an other, the space offers a possible place for this object. And, if this is true, the place can substitute for the object. The dialectic of the absence and the presence (in a here or an elsewhere) implies tis of the void and the full (in a limited or an unlimited space), where the full presupposes the void (Barthes, 1967; 1970) and receives passive or active values, coded by traits, according to systems of exchanges.

Even the most elementary organisms practice exchanges of information with their environment (Sebeok, 1991). These exchanges consist in announcing and/or perceiving a presence. The information is not, however, received without some action in return. Every presence is conjunctive or disjunctive, familiar or strange. The other is a prey or a danger, and arouses attraction or indifference, alliance or rejection. Every organism explores its environment and tries to respond adequately to the events taking place there.

Every organism makes itself a model of its environment: a model with which it interprets the events surrounding it, just as it exhibits a reaction, a parry or an evasion. Responding to what happens, averting the danger or seizing the prey, then means organizing positions and distances, and bringing forward appearances. A fairly advanced organism misleads its prey or wards off danger by appearing to merge with its setting. Resemblances can be deceptive.

The capacity for processing information depends on the capacity for filtering information material. The structure of an organism is defined by its boundaries; these form an interface that organizes the exchanges between an individualized internal space and a surrounding exterior which is the source of information and the site of assimilable energy-bearing materials. Every organism lives by activities of exploration and active collection; the energy-receiving systems, the information system, and the system of action on the environment are interdependent. Transport, positioning and orientation are behaviors of approach to and avoidance of a source of energy or information. To ensure the coherence of its actions, the organism must extract invariants from its sensory universe and transform sensory energy into information.

The human being, as an advanced organism, develops rules of behavior from its models of the environment, rules that enable it not only to interpret current events and ward off the dangers of the present world, but also to make hypotheses about future events and to propose a vision of possible worlds in which those dangers would be averted, a vision in which variations of form might be related to the measure of invariant forms.

These possible worlds are projected on the basis of an interpretation of events traversing existing systems of relations; they are sketched in a prefiguration in which to be together supposes the sense of a beyond. By the projection of relations between identity and difference the danger is sublimated; it is controlled in the relations instituted between the here and the elsewhere. The semiotics of human space thus fits well, as Saussure wished, into a social psychology. It shows how such psychology is territorial.

Thus the semiotic function begins with the capacity to anticipate a relation between actions and to infer one from the other (Piaget, 1978). Representation extends space beyond the limits of the perceptual field, and permits not only the imagining of an object in its absence, but the internalizing of an action (semiotic function) and the expression of adapting of the actions to objects that resist them (pragmatic function).

In space, objects are not merely perceived by a reading of their respective properties, but gain meaning through the actions applied to them (Piaget and Inhelder, 1947). The perception of the material reality of things concerns their topic neighborhoods. It reconstructs upon symbolized objects the result of an action in the space of real objects (Piaget and Inhelder, 1947). In this sense, resulting from action, it is a reproduction of a form, the principle of the existence of objects for us, beyond our immediate perceptual field (Pellegrino, 1985). The links between actual and virtual space distinguish links in absentia and links *in praesentia* for the knowledge of a place.

The link between the actual object and virtual objects can also be conceived as the link between the actual process and the system of places that makes it possible. Within the space of our relations it refers to the link between possible places and occupied positions. The position is the result of the action of positioning, like putting the object in an empty existent place, in the sense that it occupies space in comparison to other positions. One can thus better understand how the fact of positioning is articulated and extended by the fact of the available places, in the sense of having places to distribute objects as means to a potential action. The way of positioning is also a way of opposing; in positioning an object, one has to impose it and sometimes remove another object, sometimes even displacing an opposing object to the point of threatening the other's position (Pellegrino, 1986).

The available place is bounded in reference to others according to a grammatical form giving to the placed object an *emerging surface* (Foucault, 1969), a value and rules regulating other objects occupying different positions. The different places are thus structured by spaces that determine them: there is a space of centration (from which the subject acts), a space of objects (which is aimed at by the subject), and a space of reference (in relation to which the subject situates himself and evaluates his action). Spaces of centration, spaces of object and spaces of reference determine places that are superimposed or mutually excluded, that are intertwined or intersected, open or closed to each other. These places offer virtual positions ordered in their connexities and disconnexities by the partition and composition of spaces.

Playing upon the availability of places, positioning becomes specific by resemblance or difference, by analogy or homology, in a classification or a hierarchy. Thus they establish actual links with others: according to composition within a neighborhood, according to complementary relations between intercalated and ordered positions, according to functional or formal relations, according to oriented and equilibrated flows. There are four modes of spatialization: topic (composition and decomposition of places); iconic (resemblances and differences between them); quantic (numeric and metric quantities); and organic (formal locations and functional attributions). Each position in a place is thus actualized by two opposing modes (Pellegrino, 1992).

Attribution procedures take origin in the synthesis of partition (decomposition), displacement (relation), and comparison (transposition), which aim at measuring the content of the sets in question. Positionings themselves are not always static. They can also be dynamic and connected by displacements. The routes they take, such as flows and diffusions, back-and-forth movements, avoidance and crossing, focalizations and polarizations, are supports of placements in correspondence (references and inferences).

With these coexisting modes of spatialization, spaces impose their structures upon meaning. Much more, these modes of spatialization are sources of speech and writing: in the grammar that composes a

Figure 1 A centered place articulating the encounter of several spaces by superpositions and multiple intersections.

Figure 2 A centered place by inclusion (embedding) and exclusion (intercalation). By the articulation and the superposition of these two modes of spatialization, the most centered place in one space is at the same time excluded by the others.

sentence, in the economy of a text, in the path of a discourse, in the tropes in which reinforcements and transgressions are formed, as in the poetic work of a language (Pellegrino, 2000). Within forms of simultaneity and succession, they impose a grammar, with syntactic rules of composition, conjunction, and disjunction of combinative elements; a grammar that offers possible positions in a succession ordered by a system of places that imposes a beginning and an end, intervals inside of which, according to the norms of speaking a language, sequences of utterance have to complete a well-formed whole, expressing a well-conceived, just as much as well-expressed, argument.

But the spatialization of language, its expansion and the distribution of its constituents in a text, also expresses a style. The frequency of terms employed in a text, their sequence, and their iteration form a complex stylistic space. The assemblage of linguistic elements follows therefore several regimes of places: that of the rules of the grammatical correction of the sentence; that of the order descriptions and arguments stated in the narration or the discourse; that of their stylistic distribution in the parts of the text.

Indeed, it seems therefore reasonable to affirm that the semiotics of space, linking up with the semiotics of time, lies at the very foundation of all semiotics (Prieto, 1995). If the one does not exist, nothing exists (Plato, 370 B.C.). Separation, the basis of all space, precedes order, the basis of all argument. Unification of the separated as separated, composition of the multiple, exists as the condition of all possible inference, calculation of the diverse. And therefore nothing exists without space. The extent, the substance which, once informed and transformed by man, becomes space, i.e. the form which, by reason of its articulations, may be of use with a view to meaning (Greimas, 1976). Space reduces the complexity of the extent with the divisions that it effects in its articulations of meaning.

While the Spanish language is pre-eminently the language of Spain that, according to the 1978 constitution, all Spaniards (approximately 40 million) have the duty to know and the right to use throughout the national territory, some 40% of Spanish citizens also use at least one other language. Post-Franco Spain has emerged as a decentralized and plurilingual state with advanced language planning legislation. Turell (2001) distinguishes between, on the one hand, what she terms 'established' minority languages, which are

Figure 1 Major minority languages.

Catalan, Basque, Galician (all three co-official with Spanish in the territories where they are spoken) (Figure 1), Asturian (*bable*), Aragonese (*fable*), Aranese (Gascon), Romani (*caló*), Jewish, and sign language, and, on the other, those which belong to recent immigrant communities (for example, Arabic variants, English, Portuguese). The Constitution left the task of defining what counts as a minority language to Spain's Autonomous Communities, which, through statutes and language planning laws drawn up in the early 1980s, have been extremely proactive in promoting individual languages and varieties of these languages. (For a review of this legislation, see Siguan, 1992, and Mar-Molinero, 2000.)

Nonetheless, these (often considerable) efforts have not always succeeded in halting or reversing language shift toward Spanish. In 2001, for example, UNESCO modified its classification of Galician from 'potentially endangered language' to 'endangered language' as inter-generational transmission was failing. This is also the case for Basque; however, the Basque-medium element of the education system has in part compensated for this loss by creating first-generation speakers of the language. Of all the established minority languages in Spain, Catalan is the most vital, and with the expansion of the EU it is fighting for recognition as an official language; yet scholars (see, for example, Atkinson, 2000) see considerable danger in the long term from its powerful contact neighbor, Spanish.

Spanish is a major world language with more than 400 million speakers over four continents, who largely share a supra-regional norm and a broadly phonemic orthography, although, as Butt and Benjamin (1994: vii) note, it is relatively unstandardized compared to, say, French and German. Standardization is partly regulated by the language academies (of which the *Real Academia Española* is one of 22 representing the whole Spanish-speaking world) and largely by style guides (*libros de estilo*) used by the media and certain professions such as clinical medicine. With an estimated 30 000 new terms entering the language each year, many of which are short-lived in areas such as information technology, these institutions play an important role in adjudicating between competing variants. A prime mechanism in Spanish for lexical creation is the assimilation of borrowings, principally nowadays from English, through affixation. For example, 'to scan (a document)' is assimilated to the phonology and morphology of Spanish by pre- and suffixation in *escanear* (to scan), *un escaneo* (a scan), *un escáner* (a scanner). Such processes are contributing to a degree to the regularization of the language. All new verbs are in the *–ar* conjugation, and some of these are even displacing *–er* and *–ir* variants; for example, *promocionar* is ousting *promover*. In Spain, regional variation, while still present, is giving way through dialect levelling to social variation. The principal regional distinction is between northern varieties of Spanish, which distinguish in their pronunciation between *caza* /kaθa/ and *casa* /kasa/ and the southern varieties, which, like those of Latin American Spanish, are characterized by *seseo* and make no such distinction. The other main distinguishing feature, the *yeísmo* of the southern varieties (an absence of opposition between *pollo* and *poyo*; the north would use /poʎo/and /pojo/), is now permeating northern Spanish.

Prominent in the latter quarter of the twentieth century has been the emergence of user-related varieties of the language, such as the language of young people (e.g. *cheli*). Notable also has also been the use of Spanish to reflect an increasing egalitarianism rather than the sharp social stratification of, say, the Francoist period. This can be seen in the widespread use of the familiar T pronoun (*tú, vosotros/as*), with formal V (*Vd./Vds.*) now primarily used to mark deference to age or the constraints of a formal domain (such as certain types of meetings). It can also be seen in the vastly increased use of gender-neutral language in, for example, the media. Spanish speakers have been much quicker than say, the French, to create and adopt feminine forms of certain professions to refer to their female incumbents, e.g. *la primera ministra* (see Stewart, 1999: 31ff).

Spain has recognized the need to promote Spanish both in international organizations (where it does not enjoy the same status as, say French or English) and as an important second language that is currently growing in strength. In 1991 it followed the example set by institutions such as the Alliance Française, the Goethe Institut, and the British Council and started setting up a network of *Institutos Cervantes* throughout the

world as well as a website dedicated to the promotion of Spanish.

Spain: Lexicography in Iberian Languages

R Saurí Colomer, Brandeis University, Waltham, MA, USA

© 2006 Elsevier Ltd. All rights reserved.

Introduction

Spain has seven main autochthonous languages that are currently recognized to different degrees: official (Spanish), co-official with Spanish in some of the areas where they are spoken (Catalan, Basque, Galician), locally recognized as co-official (Aranese), and not officially recognized (Asturian, Aragonese). Starting in medieval times, historical events consolidated Spanish as the language of culture in most of the regions forming present-day Spain. That fact gave rise to a diglossic situation in which Spanish was assumed as the high variety (used in official and written domains), while the other languages were relegated to low and spoken registers. Hence, whereas lexicography in Spanish shows a development very similar to other socially healthy Romance languages, the linguistic diglossia influenced the cultural development of the other languages mentioned above, and consequently also their lexicographic tradition. Except for Catalan, which managed to counteract the diglossic effect to a greater extent than the other languages, the lexicographic output of most of the minority languages in present-day Spain has been hindered for a long time by the social and political dominance of Spanish.

Spanish

The earliest works on the Spanish lexicon were medieval glosses such as the *Glosas Silenses* (c. 10th century) and Mozarabic and Latin–Spanish alphabetical glossaries, which date between the 12th and 15th centuries. The Renaissance was characterized by the proliferation of Latin–Spanish dictionaries (which laid the foundations for later monolingual dictionaries), bilingual dictionaries between Spanish and other modern languages, and specialized vocabularies in areas like medicine or agriculture. A noteworthy work of that period is *Universal vocabulario en latín y en romance* by Alfonso de Palencia, which was published in 1490 and is considered a link between medieval and modern lexicography. The most remarkable works are, however, the two dictionaries authored by Elio Antonio de Nebrija, which initiated a new lexicographic tradition. They are the *Vocabulario latino-español* and the *Vocabulario español-latino*, and were compiled in 1492 and 1495, respectively.

The earliest monolingual general dictionaries were compiled in the 17th century; the most prominent of these was *Tesoro de la lengua castellana* (1611) by Sebastián de Covarrubias. Beginning in the 18th century, there was a general perception among intellectuals that Spanish was declining as a language of culture (the so-called Golden Century in Spanish literature had been two centuries earlier), and this feeling led to the creation of the Spanish Royal Academy

world as well as a website dedicated to the promotion of Spanish.

Spain: Lexicography in Iberian Languages

R Saurí Colomer, Brandeis University, Waltham, MA, USA

© 2006 Elsevier Ltd. All rights reserved.

Introduction

Spain has seven main autochthonous languages that are currently recognized to different degrees: official (Spanish), co-official with Spanish in some of the areas where they are spoken (Catalan, Basque, Galician), locally recognized as co-official (Aranese), and not officially recognized (Asturian, Aragonese). Starting in medieval times, historical events consolidated Spanish as the language of culture in most of the regions forming present-day Spain. That fact gave rise to a diglossic situation in which Spanish was assumed as the high variety (used in official and written domains), while the other languages were relegated to low and spoken registers. Hence, whereas lexicography in Spanish shows a development very similar to other socially healthy Romance languages, the linguistic diglossia influenced the cultural development of the other languages mentioned above, and consequently also their lexicographic tradition. Except for Catalan, which managed to counteract the diglossic effect to a greater extent than the other languages, the lexicographic output of most of the minority languages in present-day Spain has been hindered for a long time by the social and political dominance of Spanish.

Spanish

The earliest works on the Spanish lexicon were medieval glosses such as the *Glosas Silenses* (c. 10th century) and Mozarabic and Latin–Spanish alphabetical glossaries, which date between the 12th and 15th centuries. The Renaissance was characterized by the proliferation of Latin–Spanish dictionaries (which laid the foundations for later monolingual dictionaries), bilingual dictionaries between Spanish and other modern languages, and specialized vocabularies in areas like medicine or agriculture. A noteworthy work of that period is *Universal vocabulario en latín y en romance* by Alfonso de Palencia, which was published in 1490 and is considered a link between medieval and modern lexicography. The most remarkable works are, however, the two dictionaries authored by Elio Antonio de Nebrija, which initiated a new lexicographic tradition. They are the *Vocabulario latino-español* and the *Vocabulario español-latino*, and were compiled in 1492 and 1495, respectively.

The earliest monolingual general dictionaries were compiled in the 17th century; the most prominent of these was *Tesoro de la lengua castellana* (1611) by Sebastián de Covarrubias. Beginning in the 18th century, there was a general perception among intellectuals that Spanish was declining as a language of culture (the so-called Golden Century in Spanish literature had been two centuries earlier), and this feeling led to the creation of the Spanish Royal Academy

(*Real Academia Española,* RAE) in 1714. RAE compiled two outstanding dictionaries. Between 1726 and 1739 it published *Diccionario de Autoridades*, remarkable in its time for its extensive use of literary and scientific sources and its coverage of both medieval and contemporary language. Forty years later, in 1780, RAE also published *Diccionario de la lengua castellana* (*DRAE*), a dictionary that had been initially conceived as the short version of *Autoridades,* but that ended up being used as the basis for several monolingual Spanish dictionaries. DRAE identified Castilian Spanish as the standard for Spanish until its 15th edition (1925), when regionalisms from other Spanish-speaking areas in Spain and America were also introduced.

Other dictionaries of that period are also worth noting, such as *Diccionario castellano con las voces de ciencias y artes,* compiled by Esteban de Terreros between 1786 and 1793, a dictionary that has been frequently neglected but which is of indisputable lexicographic value. From the 19th century, *Nuevo diccionario de la lengua castellana*, compiled in 1846 by Vicente Salvá, and *Diccionario nacional o gran diccionario clásico de la lengua española*, published by Ramón Joaquín Domínguez in 1847, are today considered leading exponents of the best lexicography developed during that time.

The 20th century was a period of large and exceptional lexicographic productions. Among them we note *Diccionario de construcción y régimen de la lengua castellana,* an eight-volume dictionary devoted to Spanish syntactic constructions, authored by Rufino José Cuervo and published throughout a period of more than 100 years (between 1886 and 1988). Equally worthy of mention are the two multivolume etymological dictionaries, *Diccionario crítico etimológico de la lengua castellana,* edited by Joan Coromines between 1954 and 1957, and *Diccionario críticio etimológico castellano e hispánico*, compiled between the years 1980 and 1991 by Joan Coromines and José A. Pascual. Also worth mentioning is Samuel Gili Gaya's *Tesoro lexicográfico* of 1947, which is a thesaurus of all Spanish dictionaries that had been published between 1492 and 1726. In addition to these remarkable works, Spanish lexicography in the 20th century also experienced a proliferation of general-user dictionaries, the most notable of which are the *Diccionario de uso del español*, by María Moliner, published in 1966, and *Diccionario del español actual* by Manuel Seco and his colleagues, which appeared in 1999. Function-specific dictionaries (synonyms, inverse, terminology, or neology), and bi- or multilingual dictionaries were also compiled at that period. A number of dictionaries were published in electronic format, like DRAE 1992 edition or Moliner. Moreover, RAE started working on corpus linguistics-based projects for lexicography, and now its two corpora of historic and contemporary Spanish (CORDE and CREA) are available online, together with a database system (called BusCon) for dictionary look-up.

Catalan

As in Spanish, medieval lexicography in Catalan is represented by glosses and Latin– or Hebrew–Catalan alphabetical glossaries (14th–15th centuries). The Catalan Renaissance also parallels the Spanish one in that it is characterized by the compilation of specialized glossaries, modern language bilingual vocabularies, and Latin–Catalan dictionaries. Within this period, we find Joan Esteve's *Liber elegantiarum*, which appeared in 1489 and is the first Catalan vocabulary with lexicographic intention, and Gabriel Busa's *Diccionari llatí-català i català-llatí*, 1507, which is based on the lexicographic work in Spanish by Nebrija. Onofre Pou's dictionary, entitled *Thesaurus puerilis* and published in 1575, is also worth noting in that period because of its influence on subsequent work.

At the end of the 15th century, political developments brought Catalan into an acute diglossic situation that led to the so-called 'Decadence.' Lexicographic work in Catalan during this period is represented by only three Latin–Catalan dictionaries: *Fons verborum et phrasium* by Antoni Font (1637), *Thesaurus verborum ac phrasium* by Pere Torra (1640), and most remarkably, *Gazophylacium catalano-latinum* by Joan Lacavalleria (1696). All of these remained influential throughout the next century. The Decadence extended into the 18th century, when Catalan was banned from legal and educational spheres. The perception of decline resulted in dictionaries that aimed at preserving the language. At that same time, the claims of a Port Royal-inspired movement in favor of using the student's own tongue for teaching, led by Baldiri Rexach, motivated the authors of a number of Catalan–Spanish dictionaries. Under the Enlightenment influence, there were attempts to emulate RAE work in several unsuccessful projects, but no monolingual dictionary of Catalan was ever published during that period.

The 19th century is known as the *Renaixença* (literally, 'rebirth'). There was an enthusiasm for reviving Catalan as a language of culture, which was reflected in the proliferation of dictionaries, both

dialectal and general. Noteworthy works of that period are the two-volume *Diccionario catalán-castellano-latino*, a collective work published between 1803 and 1805 by Esteve, Bellvitges, and Juglà, and *Diccionari de la llengua catalana*, 1839–1840, by Pere Labèrnia, which is considered the dictionary of the *Renaixença*. Both of them are trilingual (Catalan–Spanish–Latin). Further, the positivist tendencies of those times led to the compilation of comprehensive dictionaries on historic-comparative principles. Good examples are the posthumously published compilations of Marià Aguiló and Josep Balari. This interest extended into the initial decades of the 20th century and culminated with the impressive work of Josep Maria Alcover and Francesc de Borja Moll: the 10-volume *Diccionari Català-Valencià-Balear*, which was published between 1926 and 1962. *Alcover-Moll*, as it is popularly called, is a unique work among all Romance languages. It covers all Catalan dialects (old and modern), and provides etymological, patronymic, and toponymic information.

A major concern among Catalan intellectuals at the beginning of the 20th century was to establish a prescriptive standard for Catalan that would help consolidate it as a modern language. This resulted in Pompeu Fabra's *Diccionari general de la llengua catalana*, a 1932 dictionary that was regarded as normative by the Institute for Catalan Studies (*Institut d'Estudis Catalans*, IEC). Other major concerns in 20th-century Catalan lexicography were avoiding Spanish interference, communicating with other languages, and normalizing Catalan in all spheres, including technical and scientific fields. After Franco's death, these concerns led to a profusion of monolingual, bilingual, terminology, and neologism dictionaries, many of which are available in electronic format.

The main monolingual onomasiological dictionaries today are Enciclopèdia Catalana's *Gran diccionari de la llengua catalana* (1998) and *Diccionari de la llengua catalana* (1995), which is a normative dictionary compiled by IEC based on Fabra's work. More function-specific products also exist (synonym, abbreviation, pronunciation, frequency, and inverse dictionaries), as well as unique works, like the nine-volume etymological *Diccionari etimològic i complementari de la llengua catalana*, published between 1980 and 1991, and the six-volume *Onomasticon Cataloniae*, published between 1989 and 1997. Both were authored by Joan Coromines. IEC is currently sponsoring the ambitious project of a corpus-based, comprehensive, and descriptive dictionary of contemporary Catalan.

Galician

Early diglossia in Galicia had already placed its culture in a weak situation in the Middle Ages. Until the 18th century there was only one Galician vocabulary, compiled c. 1536 by Bachiller Olea. The 18th century featured the work of three unpublished lexicographers: Martín Sarmiento, who reached a level unsurpassed until the 20th century; Juan Sobreira, who conceived a dictionary based on DRAE; and Xosé Andrés Cornide. The first published dictionaries appeared in the second half of the 19th century, during a movement favorable to Galician regeneration. They were *Diccionario gallego-castellano,* published by Francisco Javier Rodríguez in 1863; *Diccionario gallego*, authored by Juan Cuveiro in 1876; and *Diccionario gallego-castellano* (1884) by Marcial Valladares. These three dictionaries, which still took Spanish as a point of departure, were of lower quality than the unpublished lexicographic work of the previous century.

Lexicographic production in the 20th century experienced a rebirth in the post-dictatorship 1980s. The first dictionaries completely in Galician appeared at this time. In 1982 Galician attained status as a joint official language, and orthographic standards were created by the Royal Galician Academy (*Real Academia Galega*, RAG) and the Galician Language Institute (*Instituto da Lingua Galega,* ILG). In 1986, two remarkable general dictionaries were published by private companies (Estravis and Xerais). The first normative dictionary, *Diccionario da Lingua Galega,* was compiled by RAG and ILG in 1990. More specialized dictionaries (learners', bilingual, synonyms) appeared in the 1990s, together with terminological vocabularies. However, Galician lexicography of that period reflected the social controversy regarding the official orthographic norm, which was accused of being based too much on Spanish and too little on a Portuguese or a more genuine historic-etymological view.

Currently, Galician lexicography is benefiting from corpus projects like CORGA and the Corpus of Modern Galician, which provided the evidence for the *Tesouro Informatizado da Lingua Galega*, which is available online.

Basque

Basque lexicography has been affected by the fragmentation between Eastern and Western dialects (spoken in French and Spanish domains, respectively) and by the diglossic situation of the language, which meant that Basque was not a written language, and

therefore was not used in official and scientific domains, until the 16th century. These facts made codifying Basque a controversial task, which is reflected in its lexicographic tradition. The first dictionary was an unpublished Basque–French work by Silvain Pouvreau, dating from the 17th century, which covered only Eastern dialects. A century later, in 1745, Manuel Larramendi published *Diccionario trilingüe del castellano, bascuence y latín*, a Castilian–Basque–Latin dictionary that included all dialects and introduced several neologisms to fill onomasiological gaps in technical and scientific domains. Worth mentioning in the 19th century are José Francisco Aizkibel's Basque–Spanish *Diccionario basco español euskeratik erderara biurtzeko ì̀ztegia*, which appeared in 1883, and *Dictionnaire basque–français*, the unpublished Basque–French dictionary by Maurice Harriet. At the beginning of the 20th century, in 1905, the two-volume *Diccionario vasco–español–francés* by Resurreción María Azkue was published. This remarkable dictionary is trilingual and contains oral, written, dialectal, and historical data as well as some new terminology.

A unified orthography for Basque was approved by the Basque Academy (*Euskaltzaindia*) in 1968, and the first monolingual dictionaries for Basque appeared in the 1980s. They are *Gaurko euskara idatziaren maiztasun hiztegia*, a dictionary of frequencies edited by Ibon Sarasola in 1982, and *Hauta-lanerako euskal hiztegia*, also by Sarasola, a dictionary based on the literary tradition from 1750 to 1964 and published between 1984 and 1995. Euskaltzaindia has recently published the eight-volume *Diccionario general vasco*, *Orotariko euskal hiztegia* (1987–2004), a descriptive and general dictionary of Basque compiled from a diachronic corpus that is available on CD-ROM. Euskaltzaindia is currently working on a normative unified lexicon (*Hiztegi batua*). Work on terminology and neologisms is also being carried out mainly by UZEI (Basque Centre for Terminology and Lexicography). Its most important product is *Euskalterm*, a publicly available terminological database. Other more function- and audience-specific dictionaries have also been produced, mostly by private companies.

Asturian

The first known attempts to compile an Asturian dictionary were made in the 18th century by Gaspar Melchor de Xovellanos, Francisco Caveda y Solares, and Carlos González de Posada. Their work, most of it now lost, remained unfinished and unpublished. Language codification was also a major concern for 19th-century intellectuals in Asturies. Several of them, such as Juan Junquera Huergo and Julio Somoza, developed lexicographic work aiming at a standard dictionary, but this too remained unpublished. Only dialectal compilations were published in that century, along with the first Asturian–Galician dictionary, *Vocabulario de las palabras y frases bable*, by Apolinar Rato y Hevia de Argüelles (1891), which has been widely criticized for its inaccuracy.

The first half of the 20th century featured other unpublished dictionaries (by Pepín de Pría and Fernán Coronas, among others) and several dialectal glossaries, some of remarkable quality, such as *Vocabulario del bable de occidente*, by Bernardo Acevedo y Huelves and Marcelino Fernández y Fernández, and *El bable de Cabranes*, by María Josefa Canellada. After the dictatorship, the production of dialectal glossaries increased, and a considerable number of Asturian-Spanish dictionaries were published. In 1980, the Asturian Language Academy (*Academia de la Llingua Asturiana*, ALlA) was founded, and in 1981 it established the Asturian orthographic norms. Also significant is the fact that some publishing companies, such as Trabe, started developing work on Asturian lexicography in a consistent way. In 2000, ALlA published the first normative dictionary, *Diccionariu de la Llingua Asturiana,* a general dictionary that includes new terminology and neologisms. Other important works are the Asturian–Spanish bilingual dictionary *Diccionariu asturianu-castellanu, castellanu-asturianu* compiled by Juan José Vicente in 2002, the remarkable *Diccionario general de la lengua asturiana*, a dialectal dictionary published in 2003 by Xosé Lluis García Arias, and the *Diccionario de sinónimos y equivalencias castellano-asturiano*, a dictionary of synonyms appeared in 2004 and authored by Luis Alberto Prieto García. A large-scope etymological dictionary is currently being developed by Xosé Lluis García Arias.

Aragonese

Glosas Emilianenses (11th century), which has long been considered to be written in Spanish but is, in fact, written in Aragonese, constitutes the first lexicographic work (and written text) of a Romance language in the Iberian Peninsula. Despite such an early production, the decline of Aragonese power in the 15th century caused the cultural recession of that language and resulted in an extremely sparse lexicographic production until the 19th century. The vocabulary of Gerónimo de Blancas, *Índice donde se declaran*

algunos vocablos aragoneses, appeared in 1641 and is the only work worth mentioning for that period.

In the 19th century, two Aragonese–Castilian dictionaries were published: *Ensayo de un diccionario aragonés-castellano*, compiled in 1836 by Mariano Peralta, and *Diccionario de voces aragonesas*, compiled in 1859 by Jerónimo Borao. Other bilingual or dialectal vocabularies attest a renewed interest in Aragonese at the beginning of the 20th century. However, during the Franco dictatorship, Aragonese lexicography was developed mainly in the domain of academic research. Such is the case of the vocabulary *Vocabulario del alto-aragonés* by Pedro Arnal (1944) and two Antoni Maria Badia i Margarit works, *Contribución al vocabulario aragonés moderno* (1948) and *El habla del valle de Bielsa* (1950).

After Franco's death, there was a gradual increase of lexicographic production. In 1987, Aragonese orthographic norms were approved. There were a number of dialectal vocabularies and terminological lexicons that appeared, either published independently or as part of wider works, such as *Gran enciclopedia aragonesa* (*Great Aragonese Encyclopedia*). Several Aragonese–Castilian dictionaries appeared at that time, including *Diccionario aragonés. Aragonés-castellano y castellano-aragonés* (1992) by Rafael Andolz Canela, and the *Vocabulario básico bilingüe aragonés-castellano y castellano-aragonés* (1997) by Antonio Martínez Ruiz. Nevertheless, no general monolingual dictionary exists yet. The project *Tresoro d'a Luenga Aragonesa*, currently ongoing, aims at creating a public-domain database containing all Aragonese words in texts published between the 17th and 20th centuries. Its initial product is *Endize de bocables de l'aragonés*, an index of 90 000 inflected forms that was published in 1999 by the Institute for High Aragon Studies (*Instituto de Estudios Altoaragoneses*); this work is also available on CD-ROM.

Aranese

Lexicographic work in Aranese started late and is scarce. In fact, Aranese was not a written language until the end of the 19th century. At that time, some Occitan and Gascon dictionaries had already been compiled, but none on the Aranese dialect existed. The first works on Aranese lexicon appeared in the 20th century: Jusèp Condò Aranese's vocabulary (1914) appeared in *Butlletí de dialectologia catalana* (Bulletin of Catalan Dialectology), and *Vocabulario aranés*, the dissertation of Joan Coromines, was published in 1931. Aranese orthography was created in 1983 based on the norms of the Institute for Occitan Studies (*Institut d'Estudis Occitans*). In the 1990s, the *Conselh Generau d'Aran* (Aranese Government) published several dictionaries of different kinds, including *Petit diccionari*, an Aranese–Spanish–Catalan–French general dictionary by Frederic Vergés, and other terminological works, most of which are at least trilingual (Aranese–Catalan–Spanish) because of the Aran Valley political situation.

Spanish

R Wright, University of Liverpool, Liverpool, UK

© 2006 Elsevier Ltd. All rights reserved.

Spanish is the standard language of over 300 million people in Spain, Equatorial Guinea, and 18 states in Latin America; it is also widely used in the United States, Israel, and in Western (former Spanish) Sahara. The standard is based on, and almost identical with, the Romance speech of Old Castile, which is why non-Castilians tend to call it *castellano* rather than *español* and sometimes resent its privileged status; for according to the Spanish constitution, all Spaniards have the obligation to learn it and the right to use it, which has made both its use and its name serious and even dangerous political issues in areas where many people are native speakers of another language (*see* **Catalan; Basque**), or of the *bables* of Asturias.

History

The Romans came to Spain during the Punic Wars of the late third century B.C. Their language has been spoken in the Peninsula ever since (*see* **Latin; Romance Languages**). Iberian Romance languages only began to acquire separate names and identities in the 13th century; until then it is simplest to envisage one single though heterogeneous Romance speech community throughout the Peninsula. The Romance (*mozárabe*) of bilingual Arabic–Romance areas was probably barely influenced by Arabic and similar to that of Christian areas. The traditional writing techniques survived as the official written standard till the early 13th century, but the techniques used then in the first texts exclusively prepared in the new written form ('Old Spanish') are based on unofficial experimentations that can be traced from the 11th century. Later in that century it was decided in the Kingdom of Castile (which included Leon and Galicia) to base their written standard on the speech of Castile. This written standard was extended to Aragon and Catalonia after the union of Spain in 1479, even though Aragonese and Catalan already had written standards of their own, and was the only written form exported to the New World. In the 18th century the newly founded Spanish Academy standardized written Castilian almost definitively. The spread of spoken Castilian is less easy to chart; many people fluently speak Catalan, Aragonese, Leonese, or Galician, but read or write only Castilian.

Phonetics and Phonology

Standard Castilian has 18 consonantal phonemes: /b, p, d, t, g, k, f, θ, s, x, tʃ, m, n, ɲ, l, ʎ, ɾ, r/. /ʎ/ has almost entirely delateralized to merge with /j/, often realized as [ʒ] or [dʒ]; word-initially it derives from /pl-/ or /kl-/ (e.g., Latin *clavem*, Spanish *llave* 'key'; cf., Portuguese *chave* ([ʃ-]), Italian *chiave* ([kj-]), French *clef*). Voiced plosives occur only breathgroup-initially or after nasal consonants, being so outnumbered by the fricative allophones used elsewhere that some linguists prefer to annotate the phonemes as /*β*, ð, *γ*/. Preconsonantal nasals are homorganic. /s/ is realized [z] before a voiced consonant. In most of Andalucia and all of America there is no distinction made between /θ/ and /s/; usually they merge as syllable-initial [s] and syllable-final [-h] (or ø), but in parts of rural Andalucia as [θ]. The phonemic status of the two semi-vowels /w/ and /j/ is controversial; they might be allophones of /u/ and /i/, respectively. There are only five vowels: /a, e, i, o, u/. Rising diphthongs are much more common than falling. Schwa is not found, but synalepha at word boundaries is normal (*diez y once* /djeθionθe/ [djéθjónθe] 'ten and eleven'). The preferred syllable structure is CV (ca., 56% of syllables), which overrides word boundaries (e.g., *cual es*, 'which is' [kwa + les]). Stress is largely predictable, given morphological information; many monosyllables are clitic. Intonation rarely varies more than an octave.

Morphology

The only nominal inflection is plural marking [-s] (postconsonantally [-es]). All nouns in use have to be either masculine or feminine gender, and adjectives display number and gender concord. There is an extensive system of verbal inflections; verbs are marked for number and person concord with their subjects. Several paradigms are in opposition according to mood, aspect, relative time, and subjective attitude, in ways still not entirely understood. The citation form is the infinitive, which always ends in a stressed theme vowel + [-r]. The majority end in [-ár], including all neologisms other than those with the inchoative affix *-ecer*; the rest end in [-ér] or [-ír], conjugations most of whose other inflections are shared. Second person singulars tend to end in [-s], first person plurals always in [-mos], and third person plurals always in [-n]. Several verbs have systematically patterned variation in their stems, e.g., stressed [je] versus unstressed [e] (*tener* [tenér] 'to have'; *tiene*

[tjéne] 'he has'), or stem-final [θ] before front vowels versus [θk] before others (*conocer* [konoθér] 'to know'; *conozco* [konóθko] 'I know'). Irregular verbs usually belong to the [-er] or [-ir] category, combining irregular stems with regular inflections. Many verb forms employ auxiliaries, whose repertoire is numerous for progressives, while only *haber* is available for the perfect (thus *he venido pensando* 'I've been thinking'; *venir* 'come'); perfects are rarely used at all in northern Spain. Adverbs are formed off feminine adjectives with *-mente*. Derivational morphology is widely used; ostensible diminutives (*-illo*, *-ito*, and others) can be added to any nominal form with almost any meaning (depending on context and intonation); class-changing suffixes are used uninhibitedly (e.g., *-al* turns nouns into adjectives); meaningful prefixes are common, and the fashion for Verb + Plural direct object compounds with agentive meaning is spreading (e.g., *el tocadiscos*, literally 'the play-records,' 'the recordplayer').

Syntax

Sentences need no overt subject, e.g., *comíamos* 'we were eating,' *llueve* 'it's raining.' Some linguists unhelpfully postulate an underlying subject here. Adjectives follow nouns if clarifying the reference of the NP, and precede it if the reference is already clear; if in doubt, listeners take the order to be NA. There is no general fixed order of verb and noun phrases; in general, the known precedes the unknown. Thus, *Juan llegó* 'John arrived,' if John has already been discussed, and *llegó Juan* if arrivals but not John have been discussed. SV order is never obligatory; VS is obligatory in *wh*-questions, outside the Caribbean, and normal in subordinate clauses (*la casa en que vivía mi madre* 'the house my mother lived in'). OV order is obligatory when clitic pronouns accompany finite verbs (*la vi*, 'I saw her'). A preposed nominal direct object requires a clitic copy, and in speech an indirect object in any position often has the same effect. Direct objects with particular reference, if misidentifiable otherwise as subjects, take a preposed *a* (*a la reina la vio, vio a la reina*, both 'he saw the Queen'); since *a* marks both direct/and indirect objects, and several Spanish speakers make no formal differentiation between direct and indirect object pronouns either, this direct/indirect distinction may be lapsing. The only preposition that can normally link nouns within a noun phrase is a correspondingly meaningless *de*. Articles are preposed: the so-called 'definite' article (*el*, *la*, *los*, *las*) is also used in generalizations; partitive use is often marked by the lack of any article.

The use of subjunctive or indicative mood is usually grammatically determined (e.g., *pido que* 'I ask for' is always followed by subjunctive), but the so-called 'past subjunctive' can also be used in subordinate clauses for already-known material; the 'past' subjunctive (which has two usually interchangeable paradigms) is in fact atemporal. Grammatically reflexive *se* is often used with passive or 'impersonal middle' meaning (*se abrió la puerta* 'the door (was) opened'); occasionally, in VS sentences of this type but not SV, a plural subject is preceded by a verb with singular concord (sometimes *se vende manzanas*; usually *se venden manzanas*; never **manzanas se vende*, 'apples for sale'), but this is nowhere the normal usage; linguists have tried and signally failed to analyze this *se* as a subject.

Vocabulary

The most startling fact about Spanish for an English speaker is the presence of two words for 'to be': *estar* (<Latin *stare* 'stand') and *ser* (suppletively < *sedere* 'sit,' and *esse* 'be'), only approximately distinguishable as being used for individual circumstances and general statements, respectively (and roughly vice versa when used as passive auxiliaries). Linguistic atlases, currently fashionable, show that lexical usage is noticeably not geographically standardized; fish have different names, and the same word may be applied to different fish, in different ports, for example. Latin America has naturally adopted many local words of Indian provenance. Although the inherited vocabulary has been enriched by borrowings from Basque, Arabic, Catalan, French, Italian, Renaissance Latin, Nahuatl, Quechua, English, etc., most neologisms are more commonly formed via derivational morphology or semantic shift.

The Future

Spanish has wide geographical variation but remains a single speech community with a general standard for all to style-shift toward in formal situations, for the Latin–American standard is very similar to the European and will remain so, given mass communications. Local variations grow beneath the standards, however. For example, bilingual Aymara speakers in Bolivia have adopted the Aymara evidential system into their Spanish morphology, and Guarani speakers in Paraguay have adopted Guarani nominal tense-markers (e.g., *mi noviakue*, literally 'my girl-friend-past,' 'my former girlfriend'). Areas that aspirate or lose final /s/ have thereby lost a second person singular inflection and acquired homonymy with the third

person forms and use subject *tú* more in compensation; the formal second person (third person morphology, with subject *usted*(*es*)) is anyway decaying in some places but strong in others, and the system varies greatly in America. The study of linguistics in Spanish universities is now flourishing, lively, and fashionable, putting Spain (temporarily, perhaps) in the vanguard of modern Romance linguistics. There is still a great deal to discover and explain. For that reason a bibliography largely confined to English-language works is necessarily partial and parochial.

Spanish North Africa: Language Situation

Editorial Team

© 2006 Elsevier Ltd. All rights reserved.

Spanish North Africa comprises the last remains of Spanish colonialism in Africa. When Morocco became independent in 1956, Spain gave up most of its territories on the North African coast, but retained control of the cities of Ceuta and Melilla, as well as a number of smaller islands off the Moroccan coast: the islands of Alhucaimas, Velez de la Gomera, and the Chafarinas Islands, as well as the uninhabited island of Perejil, northwest of Ceuta. The Spanish claim over Perejil is strongly disputed by Morocco, and the island was under Moroccan control after an invasion in 2002. As the only part of the European Union in Africa, Spanish North Africa is attracting a considerable number of migrants from all over Africa.

Except for about 300 people on the islands (mostly military personnel), the 128 000 inhabitants of Spanish North Africa live in Ceuta (79 000 inhabitants) and Melilla (59 000 inhabitants), including 34 000 Moroccans and 1500 Jews. The official language of Spanish North Africa is Spanish, but Spoken Moroccan Arabic plays an important role as the language of the Moroccans living in Spanish North Africa, as well as those who live in Morocco, but come to Ceuta or Melilla on a daily basis for work. While the eastern part of Ceuta, for example, is culturally and linguistically Spanish dominated, the western part, closer to the Moroccan border, is strongly influenced by Arab culture and language. Arabic is also taught in schools.

Karen Spärck Jones is Professor of Computers and Information (emeritus) at Cambridge University. She is a Fellow of the British Academy, a Fellow of the American Association for Artificial Intelligence and the European Coordinating Committee for Artificial Intelligence, and a distinguished winner of the Award of Merit from the American Society for Information Science and Technology.

Spärck Jones has been active in information retrieval and natural language processing since the late 1950s. She received her Ph.D. thesis from Cambridge in 1964, on the subject of *Synonymy and semantic classification*, which was published (by Edinburgh University Press) only in 1986. Over the course of her career, she has published (including co-edited and co-authored works) seven other books. She has also made contributions to research in machine translation, the modeling of users and agents, speech applications, and automatic summarization.

Spärck Jones is a distinguished experimental scientist, with an empirical approach well-suited to the problems she has addressed. For example, in retrieving documents from a collection, an important goal is to develop a statistical measure that will identify words that will discriminate the document from other documents in a collection. Language is such that relatively few words will occur often, while relatively many words will occur rarely (a phenomenon known as Zipf's Law). In her classic 1972 paper, 'A statistical interpretation of term specificity and its application in retrieval' (*Journal of Documentation 28*, 11–21), Spärck Jones developed a measure (inverse document frequency, or 'idf') which characterizes the discriminative power of a word in terms of the inverse of the number of documents the word occurs in, thereby penalizing words that are common across documents and favoring words that are unique to a document. When idf is combined with a measure of the word's frequency in a document (called 'tf'), the result is a formula called 'tf.idf' (for 'term-frequency times inverse document frequency'). It has proved to be very widely used and cited in document retrieval, text comparison, and in general in many computational linguistics tasks that select and weight terms in a document.

Another seminal contribution has been in collaboration with Stephen Robertson (now at Microsoft Research Cambridge). In 1976, they jointly developed a probabilistic model of weighting of documents in terms of relevance to a user's information need. The Robertson–Spärck Jones weighting scheme has been incorporated into a relevance weighting formula (called 'Okapi BM25') used in most of the systems that participate in the Text Retrieval Conference (TREC), an annual conference in which the key groups working on information retrieval compare their tools on common tasks. Spärck Jones and Robertson continue to work together exploring other applications of their probabilistic model.

Spärck Jones has been influential in the design of the TREC conference, which, through large-scale collaborative experiments with a focus on evaluation, has resulted in substantial improvements in our understanding of information retrieval, in turn helping transform the way we access information. In *Evaluating natural language processing systems: An analysis and review* (Springer-Verlag, 1996), Spärck Jones and her colleague Julia Galliers have helped lay out a framework for language processing system evaluations. Spärck Jones has also made fundamental contributions to other evaluation forums, including evaluation of question-answering and automatic summarization systems.

Spatial Variation (Geolinguistics)

D Heap, University of Western Ontario, London, Ontario, Canada

© 2006 Elsevier Ltd. All rights reserved.

The awareness of one's own speech community (*see* **Speech Community**) brings with it, almost inevitably, a consciousness of those who speak differently elsewhere. In cases of languages with very small populations of speakers, this may mean being conscious of neighboring groups who use an entirely different (and unintelligible) language (*see* **Isolated Language Varieties**), but in many (perhaps most) cases, nearby communities speak varieties that are sufficiently similar to ours to be (at least in part) mutually intelligible but at the same time different enough to be noticed as such (*see* **Language Families and Linguistic Diversity; Language/Dialect Contact**). Since the ancient Greeks (at least), we have evidence that speakers of a larger area who considered themselves all speakers of 'Greek' were conscious of those who spoke 'the same language' but differently, that is, the various city-states of Ancient Greece (*see* **Greek, Ancient**):

> Thus geographic diversity was the first observation ever made in linguistics: it determined the initial shape of scientific research on language matters, even among the Greeks; true, they only paid attention to the variation among the different Hellenic dialects, but in general their interest did not extend beyond Greece itself. (de Saussure, 1983: 262, my translation)

Since most speakers' conception of what constitutes 'a language' is largely based on nonlinguistic criteria (*see* **Language Attitudes**), it is hardly surprising that laypeople's conception of what is (or is not) 'the same language' as theirs often has more to do with sociocultural or political constructs than with specific linguistic features (*see* **Linguistic Features**). This is not to imply that there are no empirical differences between neighboring varieties but rather that those features that are selected (from among many possible differences) as representing a distinction between geolects are typically quite an arbitrary set (*see* **Ethnicity**).

Variation in Animal Communication

Within animal communication systems we find regional differences in, for example, birdsongs (*see* **Dialects in Birdsongs**). That is to say, while many species seem to be genetically predestined to produce and recognize different songs, the exact forms that songs take will often vary from place to place. For certain species of birds, at least, a convincing case can be made for the ecological adaptation of certain acoustic patterns to certain types of physical environment (Handford, 1988). The analogous view of linguistic variation, a sort of 'geographic determinism' whereby the features of human speech varieties could be correlated with particular climates or terrains, gained a certain popularity in 19th-century notions of language variation but has been largely rejected by modern linguistics.

Being much more complex than even the most sophisticated systems of birdsong, human speech systems tend to vary through space in ways that are only indirectly related to geographical features (*see* **Spatiality and Language**). Since speakers' lects tend to resemble more closely the speech of those people they talk to more often and more intensely, and since physical geography is one factor among many that condition the frequency and intensity of human communication, it is natural that geographic features play a role in language variation, but this conditioning is necessarily indirect rather than causal (*see* **Environment and Language**).

Physical and Human Geography

There is obviously nothing inherent about a hilly landscape or a cold rainy climate that favors any particular set of linguistic features, but if similar geographic and climatic conditions favor (or simply coincide with) migrations and contacts among populations, then there can arise the perception of a link between physical geography and linguistic variation. This point can be illustrated by a distinction that is often drawn in Latin American Spanish (*see* **Spanish**) between what are traditionally called 'highland'

Variation in Animal Communication

Within animal communication systems we find regional differences in, for example, birdsongs (*see* **Dialects in Birdsongs**). That is to say, while many species seem to be genetically predestined to produce and recognize different songs, the exact forms that songs take will often vary from place to place. For certain species of birds, at least, a convincing case can be made for the ecological adaptation of certain acoustic patterns to certain types of physical environment (Handford, 1988). The analogous view of linguistic variation, a sort of 'geographic determinism' whereby the features of human speech varieties could be correlated with particular climates or terrains, gained a certain popularity in 19th-century notions of language variation but has been largely rejected by modern linguistics.

Being much more complex than even the most sophisticated systems of birdsong, human speech systems tend to vary through space in ways that are only indirectly related to geographical features (*see* **Spatiality and Language**). Since speakers' lects tend to resemble more closely the speech of those people they talk to more often and more intensely, and since physical geography is one factor among many that condition the frequency and intensity of human communication, it is natural that geographic features play a role in language variation, but this conditioning is necessarily indirect rather than causal (*see* **Environment and Language**).

Physical and Human Geography

There is obviously nothing inherent about a hilly landscape or a cold rainy climate that favors any particular set of linguistic features, but if similar geographic and climatic conditions favor (or simply coincide with) migrations and contacts among populations, then there can arise the perception of a link between physical geography and linguistic variation. This point can be illustrated by a distinction that is often drawn in Latin American Spanish (*see* **Spanish**) between what are traditionally called 'highland'

(*tierras altas*) and 'lowland' (*tierras bajas*) or coastal varieties, which for a number of salient features correspond respectively to more conservative north-central varieties and more innovative southern varieties of Peninsular Spanish. While a number of striking parallels can be drawn, especially between linguistic features of southern Spain and those of coastal and Caribbean Latin American Spanish, these are best understood as a result of human contact and communication: during the colonial period, the coastal areas of Latin America remained in closer commercial and social contact with the southern Spanish port of Seville, the principal center for shipping and trade with the New World. Although the Latin American highlands may have indeed received a good portion of their initial Spanish settlement from linguistically conservative central-northern Spain, if these inland varieties remained relatively distinct it was because of their lack of direct contact with the many linguistic innovations that spread from Andalusia via the shipping routes to the ports and coastal areas of Latin America.

In other words, physical geography as a factor conditioning linguistic variation is always secondary to human geography. In fact, as Britain (2002) points out, we can distinguish three different types of space: Euclidean (or objective geometric) space, social space (as shaped by human agency), and perceived space (our environments as constructed by everyday practice). Natural barriers (such as mountain ranges) or natural channels of communication (rivers, etc.) can of course play a role, but only inasmuch as they affect human interactions through trade, travel, commerce, or cultural contact. At times the same natural feature (for example, a significant body of water) can either favor or impede contact between populations, depending on whether it coincides or not with political, social, commercial, or ecclesiastical boundaries (*see* **Language Politics**) that are – or are perceived to be – significant for a given community.

Techniques for Studying Spatial Variation

According to Jaberg, 'linguistic geography' fundamentally consists in

> transposing the study of a language from a point into space, in no longer envisaging a linguistic fact as strictly localised, in its creation or in its evolution, but rather considering it in relationship with other centres of creation, placing it in its geographic surroundings, of establishing its *area*. (1947, my translation, original emphasis)

But how exactly is this abstract goal to be attained? We have an array of techniques for studying language varieties as 'points' in geographical space (Pop, 1950), with or without internal variation or stratification, but not all of these can be directly transferred to the study of the geographic dimension of language (*see* **Language Surveys**).

Although individual geolects can be (and often are) usefully depicted in monographic studies of individual speech communities (be they municipalities or entire regions), the serious examination of geographic variation by its very nature requires surveys carried out at different points across the area studied (*see* **Language Spread**). These surveys are most often of the traditional 'closed questionnaire' type (*see also* **Dialect Atlases**), although semidirected interviews have also been used successfully (cf., for example, Dulong and Bergeron, 1980; Fernández-Ordóñez, 2004). While it is possible to simply survey linguistic forms from a range of points and display the collected forms on a base map of the region studied (as done, for example, by Gilliéron and Edmont, 1902–1910 and in most traditional linguistic atlases since then; *see also* as well as **Dialects: Early European Studies**), the resulting 'display maps' can be very difficult, if not impossible, to interpret meaningfully since the mass of data cannot be synthesized coherently without reading each form on the map and comparing it with its neighbors. In practice, display maps, while traditionally considered the most faithful to the linguistic data (although the assumption that fieldworkers' transcriptions are completely 'faithful' to subjects' production is of course somewhat debatable), need to be supplemented with some additional technique for representing differences between neighboring geolects, if geolinguistic variation is to be understood with any overall coherence (*see* **Dialect Atlases**).

Isoglosses and Isogloss Bundles

Since the birth of linguistic geography in the 19th century, the most widely used mechanism for representing geographic differences in linguistic data has been the isogloss (from the Greek for 'same speech'), an imaginary line traced on a map separating points where a difference in some given feature is detected while grouping together points that share the same value for the feature in question (Pop, 1950). While isoglosses can in principle be drawn for linguistic features of any type (phonetic, phonological, morphological, syntactic, or lexical; *see* **Standard and Dialect Vocabulary**), the most common in many studies of linguistic geography have been phonetic and lexical isoglosses, which in turn correspond to those features that predominate in the most widespread conceptions

of what constitutes a 'dialect' (both from the point of view of laypeople's impression of what a dialect is and from that of traditional dialectologists' definitions): pronunciation differences and vocabulary differences.

The number of possible isoglosses is potentially very large, in theory perhaps infinite, and in practice limited by the number of items collected in the survey questionnaire or interviews, the number of features that can be isolated and mapped among these data, and above all by the time and resources that can be devoted to mapping them. Thus it is most often the case that the isoglosses corresponding to different features do not necessarily coincide neatly to delimit clear dialect areas. For this reason, special importance is traditionally given to 'bundles' of isoglosses, that is, places where a number of isoglosses coincide (or nearly so) in the zones that they separate (*see* **Language and Dialect: Linguistic Varieties**). On this view, a large number of isoglosses that fall (roughly) along the same path should indicate a significant division between dialect areas, or even related languages, while individual isoglosses (or smaller numbers of them) spread out over a given territory would represent the more gradual transitions characteristic of dialect continua or dialect chains (*see* **Dialect Chains**).

The importance attributed to isogloss bundles is, however, completely dependent on the variables chosen to map as isoglosses, a choice that is in turn determined by those features that are surveyed in the first place (i.e., included in an atlas questionnaire or gleaned from interview data). Since the features that end up separated by isoglosses are typically chosen for their (assumed) potential to differentiate geolects, the dialect zones that are delimited by isogloss bundles are, in the final analysis, somewhat circularly determined by the methods used and by researchers' input assumptions about the variables that are considered relevant. Some traditional dialectologists are reported to have traced 'dialect boundaries' amid a myriad of partially contradictory isoglosses according to their own intuition as to "where they knew they should be," based on, for example, settlement patterns or historical divisions, a procedure which thus completes the methodological circularity that underlies the whole concept of the 'isogloss bundle.' That said, there are some remarkably robust isogloss bundles that undeniably correspond to important divisions in the geographic distribution of geolectal variants, for example the large number of isoglosses that fall at the Gironde estuary where it empties into the Atlantic in southwestern France and that coincide in dividing Occitan (Languedocien or *langue d'oc*; *see* **Occitan**) from northern French (or *langue d'oïl*; *see* **French**) varieties.

Dialectometry and Electronic Cartography

Dissatisfied with the relative methodological subjectivity on which the notion of 'isogloss bundle' depends, authors of more recent studies have turned toward statistically informed methods that undertake to calculate measures of linguistic distance between geolectal varieties. Collectively called dialectometry, these methods allow for a more objective appreciation of which geolects are more similar and which are more different, but at a more basic level these analyses are still dependent on the available data used as raw input for the various calculations, data that are in turn the product of methodological choices as to which variables (linguistic forms and features) are selected to be surveyed in the first place (Goebl, 2004).

The computer technologies that make dialectometry a practical option for current research allow another important advance in our ability to understand spatial or geographic linguistic variation: automatic cartography (often called Geographic Information Systems, or GIS), which allows for the rapid production of geolinguistic maps based on geolect forms and features that are stored and organized in electronic databases. While considerable human effort is required to construct such databases and especially to populate them with consistent and accurate data, once the data are available in the appropriate digital format, they can be used to produce a wide variety of different maps, synthesizing many different linguistic variables, exploring possible correlations between different linguistic features using a range of different algorithms, and mapping their relative geographic distribution almost immediately (Kretzschmar, 1999). The time savings, compared to traditional cartographic methods, is in the range of several orders of magnitude and in practice means that researchers can explore and test geolinguistic hypotheses that are more sophisticated and more detailed than would have been imaginable in the context of precomputerized, paper-based dialectology. Data from predigital geolinguistic surveys can also be useful when collated and compared using GIS techniques, as Pato (2004) does for the morphosyntax of conditional forms in northern Spanish varieties.

These new automatic cartography methods can be applied to linguistic survey data collected specifically for this purpose, from the macrolinguistic scale of the Varilex project (Ueda and Takagaki, 1995), which allows lexical variation from major Spanish-speaking cities in more than 20 different countries to be dynamically mapped online 'on the fly' (Ruiz Tinoco,

2002) (*see* **Corpora in Studies of Variation; Spanish**, and **Standard and Dialect Vocabulary**), to the microlinguistic level of the *Atlas linguistique audiovisuel du Valais romand* (*ALAVAL*), which presents data, including audio and video interview clips, for just 52 Francoprovençal (Franco-Provençal) speakers at 26 points in one region of Switzerland and in neighboring French and Italian valleys (Diémoz and Maître, 2000; *see also* **Switzerland: Language Situation; France: Language Situation**, and **Italy: Language Situation**). Similar methods can also be applied to data collected for creating linguistic atlases of the more traditional printed kind, simultaneously yielding data for automatic cartography, which transcends the limits of the printed atlas (Bauer and Goebl, 2000; *see* **Rhaeto Romance**). Another recent approach, dialect topography, eschews direct fieldwork in favor of using postal questionnaires with a large enough number of respondents to obtain data on social as well geographic variation (Chambers, 2001).

Another technique used in representing geographic relationships in linguistic data is the gravity model, which models the effect of one geolect on another as a function of their respective population size and their distance from one another (Britain, 2002). The effect that a larger speech group will exert on a smaller one was originally based on calculations adopted and adapted (as is often the case) from human geography, but it quickly became apparent that in order to account for relations between geolects, the model needed to include a measure of preexisting linguistic similarity between the two varieties.

Whatever the sources of data available, and whatever the techniques used for displaying them on maps, it is important not to lose sight of the fact that dialect cartography is not an end in itself but rather a starting point: maps can only portray linguistic reality; real explanation requires further human interpretation of maps, in combination with social and historical knowledge of the communities in question and of course linguistic knowledge of the speech varieties portrayed (see Catalán, 1975 and Fernández-Ordóñez, 2001 for good examples of such promising methods for historical dialectology). Linguistic geography can be an important part of the puzzle of understanding language variation, but it is only part of the puzzle.

Conclusions

Whatever the methods used to study spatial variation in language and whatever the technical means used to represent the results, the basic human observations that underlie linguistic geography remain constant: the speech patterns of each community simultaneously resemble and are distinct from those of nearby communities, and as the distance between communities grows, the differences between speech varieties increase while similarities decrease. Spatial variation in language is thus intimately related to human geography as well as to language history and language management (*see* **Language Planning and Policy: Models** and **Language Maintenance and Shift**). Linguistic geography was one of the earliest areas of research in which modern linguistics set out a research program distinct from historical philology, which dominated the study of language until the mid-19th century (*see*), and it remains a field in which 21st-century research continues to contribute to our knowledge of language and linguistic varieties.

Scholars are increasingly aware of the importance of going beyond our traditional notion of language to look at how people employ a range of semiotic resources in organizing and interpreting meaning. One of these resources is space. Space is central in the creation and communication of status and power relations in many cultures, mapping a "complex web" (Massey, 1994: 265) of domination and subordination as well as solidarity and co-operation. The distribution of interacting persons in space can instantiate particular systems of social inequality, conventionalizing differences between people, and making such delineations material and substantive, as well as anchoring them within historical practice. Certain spatial configurations can make participation impossible for some. Space and place are important resources in the construction of gender relations cross-culturally, as feminist geographers and anthropologists have noted (Moore, 1986; Women and Geography Study Group, 1997; Lawrence and Low, 1990). Foucault (1977) has analyzed the role of space in social disciplining, for example, in restricting the mobility and access of certain members of society. Limitations on access and mobility are directly related to the acquisition of particular knowledge domains, language forms, and often to participation in political process. As new, technologically-mediated spaces for communication become available this process of unequal access has become recognized with the term 'digital divide.' Space is a powerful resource for making abstract relationships concrete, and for organizing hierarchies of meaning and creating essentialized, exclusive categories. However, these categories are not necessarily interpreted uniformly, nor are they unproblematically reproduced.

Spatial relationships and spatial frames of reference are cross-linguistically variable, and it is important to study language use in context. This requirement necessarily means paying attention to the space in which language is used, and how this space is organized and interpreted. What forms of language are appropriate here and who can use them? How is the interpretation of a particular language form dependent on the space in which it is produced? How is language used to express spatial relationships? How is the meaning of

Scholars are increasingly aware of the importance of going beyond our traditional notion of language to look at how people employ a range of semiotic resources in organizing and interpreting meaning. One of these resources is space. Space is central in the creation and communication of status and power relations in many cultures, mapping a "complex web" (Massey, 1994: 265) of domination and subordination as well as solidarity and co-operation. The distribution of interacting persons in space can instantiate particular systems of social inequality, conventionalizing differences between people, and making such delineations material and substantive, as well as anchoring them within historical practice. Certain spatial configurations can make participation impossible for some. Space and place are important resources in the construction of gender relations cross-culturally, as feminist geographers and anthropologists have noted (Moore, 1986; Women and Geography Study Group, 1997; Lawrence and Low, 1990). Foucault (1977) has analyzed the role of space in social disciplining, for example, in restricting the mobility and access of certain members of society. Limitations on access and mobility are directly related to the acquisition of particular knowledge domains, language forms, and often to participation in political process. As new, technologically-mediated spaces for communication become available this process of unequal access has become recognized with the term 'digital divide.' Space is a powerful resource for making abstract relationships concrete, and for organizing hierarchies of meaning and creating essentialized, exclusive categories. However, these categories are not necessarily interpreted uniformly, nor are they unproblematically reproduced.

Spatial relationships and spatial frames of reference are cross-linguistically variable, and it is important to study language use in context. This requirement necessarily means paying attention to the space in which language is used, and how this space is organized and interpreted. What forms of language are appropriate here and who can use them? How is the interpretation of a particular language form dependent on the space in which it is produced? How is language used to express spatial relationships? How is the meaning of

space revised when the same space is used for very different activities? What role does space play in understanding multiple modalities in the production of meaning? Space is an integral part of talk and an important resource in the ordering of social experience. In many societies narratives of place organize history, memory, and moral ideas (Hoem, 1993).

While not surprising that linguists and linguistic anthropologists have focused primarily on language, language is not always the most important tool in shaping habits of interpretation. Duranti has shown the importance of looking at multiple 'codes' and 'channels' in the production of meaning in "a cultural space that is never neutral" (1992: 657). Space and its allocation are often more salient guides to status relations than speech in Pacific societies (see Duranti, 1994 for Samoa; Keating, 1998 for Pohnpei). The role of nonverbal ritual in communicating ideas and making them explicit is well attested, particularly the role of space and the body in displaying and assessing social meanings as well as in organizing and interpreting frameworks of participation. Studies on social deixis have shown the importance of understanding the social organization of the space in which language is used. As Hanks (1990) shows, the interpretation of Yucatecan deictic forms equivalent to English 'here' and 'there' depends not only on immediate spatial coordinates, but on local cultural practices that enrich physical spaces with social meanings.

Correlations have been found between how space is expressed linguistically and other, non-linguistic cognitive operations, such as solving spatial puzzles or replicating spatial arrays. Languages commonly organize spatial reference into systems that have been described as relative or absolute. A relative system uses concepts like right side and left side, which are based on the body in space. An absolute system relies on cardinal points of the landscape such as north and west, and is not dependent on the body. Scholars have found a correlation between the way language is used to talk about space ("it's to the left" or "it's to the north") and the way speakers remember spatial arrays in order to recreate them (Levinson, 1992, 1996). Spatial conception is central to aspects of thinking and reasoning, and spatial metaphors are often used in talking about time, music, mathematics, emotions, and social structures. These metaphors themselves create specific cultural notions of space. It is common though not universal to find that the right side or right hand is valued over the left, and similarly that 'above' is more highly valued than 'below,' 'front' than 'back,' as spatial relationships are imbued with social value. In a typical Purum house (Burma), for example, domestic space is divided into right/left, male/female quarters, with higher value attributed to areas and objects associated with right/male and lower value associated with left/female.

Space is an important component of sign languages. In the gestural-visual system of a sign language, a set of handshapes and movements are produced within a limited signing space in the area of the head and torso. While words in spoken languages are produced sequentially, a visual spatial language makes possible a combination of simultaneously occurring components from several spatial dimensions (Klima and Bellugi, 1991). Space is used to communicate time and to indicate role and reference. Space is used in both sign and spoken languages to communicate shape, distance, size, and other relationships.

The spatial structure of buildings can embody knowledge of social relations, and reflect ideals about relationships between women and men within the family and in society. A house can serve as a "memory palace" or mnemonic key for the remembrance of the past (Fox, 1993: 4). In Maori culture spatial coordinates of a house are linked to coordinates of time (Van Meijl, 1993). Bourdieu describes the house as a book that children are socialized into through their bodies, and where they learn a particular vision of the world read by the body (Bourdieu, 1977: 90). Arbitrary social differences are spatially realized in patterns within dwellings, in ceremonial houses, and in segregated workplaces.

In the Pacific Island nation of Pohnpei, Pohnpeians use spatial relations as an important tool in formulating the local idea of social inequality. This system includes specifying the meaning of relationships between bodies in space, topographical relations of sea level and mountain heights, the built environment, and spatial relations in language (Keating, 2000, 2002). For Pohnpeians both vertical and horizontal space encode social status such that precise relative rank can be constituted by an individual's location in space. Each part of the *nahs* or feasthouse has a name and a status attached to it; specific locations as well as entryways and posts are reserved for certain high status individuals. In the feasthouse, the rank of even invisible beings is materialized; deities and ancestor spirits are located in space behind where the chief and chieftess sit, the highest and furthest inward location. Here space is a signifier for time, as the past (ancestors) is simultaneously located within the present. Although status relationships are also produced through choosing specific language forms, horizontal spatial organization is able to categorize with more specificity in this case.

New communication technologies are creating spaces for communication and new forms of access to others in ways that are altering our relationship to space and how we use language, as well as the constitution of our speech communities. The radio or telephone, for example, transcends the sound transmitting constraints of proximal space. In many parts of the world, the radio bridges not only geographical space but also the boundary between public and private space. Computer-mediated space supports new ways to manipulate language structure and performance. For the linguistic minority Deaf community, the Internet and the invention of the web camera have increased and enabled new connections between deaf people who are geographically dispersed throughout the majority hearing community. For the first time deaf people can communicate using manual visual language, in many cases their native language, across vast distances in space. Using webcams and computers for signed language, a language that depends on interpreting visual spatial relationships between hands and the body (including facial movements), involves the development of new linguistic and sociolinguistic practices, including learning about and adjusting to how virtual space is crucially different from real space (Keating and Mirus, 2003). Signers reorient deictic references to the way technology has altered relationships between multiple communicators in two-dimensional space, for example, transforming the communication of the concept 'behind' in three dimensional space to mean 'beside' in two dimensional space. Orienting to the web camera's gaze parameters, signers modify signs. The sign 'baby,' for example, (usually produced slightly above or at waist level) is produced with the hands almost at chin level. Signers exploit new possibilities for communicating messages. For example, the webcam depicts something like a hand close to the lens as very large. Signers exploit this property of the lens as a new resource – size of manual articulator – for emphasis and clarity. Other properties of the webcam permit innovations in participant frameworks and the transmission of particular types of visual information across locales. Socializing children into interpreting an image on a computer monitor as an active conversational partner and how to interact with this partner are also important aspects of the incorporation of computer-mediated space technology into the communicative practices of a community.

Space is one of the means by which society is produced and interpreted by its members. Daily behavior creating and created by institutions takes place within both temporal and spatial boundaries. Yet space is often taken for granted or ignored. We should be aware of how space can obscure certain relations of power and access as well as organize language interactions; space is not neutral or 'natural.' Semiotic systems are important instruments through which ideas about social life are produced in communities of people; the relative importance of space vs. language and how visual and verbal signs work together and in opposition, as well as the roles of individuals in this process, have only begun to be investigated.

Speaker Recognition and Verification, Automatic

S Furui, Tokyo Institute of Technology, Tokyo, Japan

© 2006 Elsevier Ltd. All rights reserved.

Principles of Speaker Recognition

General Principles and Applications

Speaker recognition is the process of automatically recognizing who is speaking by using the speaker-specific information included in speech waves (Furui, 1989; Furui, 1997; Rosenberg and Soong, 1991) to verify identities being claimed by people accessing systems; that is, it enables access control of various services by voice. Applicable services include voice dialing, banking over a telephone network, telephone shopping, database access services, information and reservation services, voice mail, security control for confidential information, and remote access of computers. Another important application of speaker recognition technology is for forensic purposes (Kunzel, 1994).

Speaker identity is correlated with physiological and behavioral characteristics of the speech production system of an individual speaker. These characteristics exist both in the spectral envelope (vocal tract characteristics) and in the suprasegmental features (voice source characteristics) of speech. The most commonly used short-term spectral measurements are FFT/LPC-derived cepstral coefficients and their regression coefficients (Furui, 1981). As for the regression coefficients, typically, the first- and second-order coefficients, that is, derivatives of the time functions of cepstral coefficients, are extracted at every frame period to represent spectral dynamics. They are respectively called the delta-cepstral and delta-delta-cepstral coefficients.

Speaker Identification and Verification

Speaker recognition can be classified into speaker identification and speaker verification. Speaker identification is the process of determining from which of the registered speakers a given utterance comes. Speaker verification is the process of accepting or rejecting the identity claimed by a speaker. Most of the applications in which voice is used to confirm the identity of a speaker are classified as speaker verification.

The basic elements of a speaker recognition system are shown in **Figure 1**. In the speaker identification task, a speech utterance from an unknown speaker is analyzed and compared with speech models of known speakers. The unknown speaker is identified as the speaker whose model best matches the input utterance. In speaker verification, an identity is claimed by an unknown speaker, and an utterance of this unknown speaker is compared with a model for the speaker whose identity is being claimed. If the match is good enough, that is, above a threshold, the identity claim is accepted. A high threshold makes it difficult for impostors to be accepted by the system, but with the risk of falsely rejecting valid users. Conversely, a low threshold enables valid users to be accepted consistently, but with the risk of accepting impostors. To set the threshold at the desired level of customer rejection (false rejection) and impostor acceptance (false acceptance), data showing distributions of customer and impostor scores are necessary.

The fundamental difference between identification and verification is the number of decision alternatives. In identification, the number of decision alternatives is equal to the size of the population, whereas in verification there are only two choices, acceptance or rejection, regardless of the population

Principles of Speaker Recognition

General Principles and Applications

Speaker recognition is the process of automatically recognizing who is speaking by using the speaker-specific information included in speech waves (Furui, 1989; Furui, 1997; Rosenberg and Soong, 1991) to verify identities being claimed by people accessing systems; that is, it enables access control of various services by voice. Applicable services include voice dialing, banking over a telephone network, telephone shopping, database access services, information and reservation services, voice mail, security control for confidential information, and remote access of computers. Another important application of speaker recognition technology is for forensic purposes (Kunzel, 1994).

Speaker identity is correlated with physiological and behavioral characteristics of the speech production system of an individual speaker. These characteristics exist both in the spectral envelope (vocal tract characteristics) and in the suprasegmental features (voice source characteristics) of speech. The most commonly used short-term spectral measurements are FFT/LPC-derived cepstral coefficients and their regression coefficients (Furui, 1981). As for the regression coefficients, typically, the first- and second-order coefficients, that is, derivatives of the time functions of cepstral coefficients, are extracted at every frame period to represent spectral dynamics. They are respectively called the delta-cepstral and delta-delta-cepstral coefficients.

Speaker Identification and Verification

Speaker recognition can be classified into speaker identification and speaker verification. Speaker identification is the process of determining from which of the registered speakers a given utterance comes. Speaker verification is the process of accepting or rejecting the identity claimed by a speaker. Most of the applications in which voice is used to confirm the identity of a speaker are classified as speaker verification.

The basic elements of a speaker recognition system are shown in Figure 1. In the speaker identification task, a speech utterance from an unknown speaker is analyzed and compared with speech models of known speakers. The unknown speaker is identified as the speaker whose model best matches the input utterance. In speaker verification, an identity is claimed by an unknown speaker, and an utterance of this unknown speaker is compared with a model for the speaker whose identity is being claimed. If the match is good enough, that is, above a threshold, the identity claim is accepted. A high threshold makes it difficult for impostors to be accepted by the system, but with the risk of falsely rejecting valid users. Conversely, a low threshold enables valid users to be accepted consistently, but with the risk of accepting impostors. To set the threshold at the desired level of customer rejection (false rejection) and impostor acceptance (false acceptance), data showing distributions of customer and impostor scores are necessary.

The fundamental difference between identification and verification is the number of decision alternatives. In identification, the number of decision alternatives is equal to the size of the population, whereas in verification there are only two choices, acceptance or rejection, regardless of the population

Figure 1 Basic structures of speaker recognition systems.

size. Therefore, speaker identification performance decreases as the size of the population increases, whereas speaker verification performance approaches a constant independent of the size of the population, unless the distribution of physical characteristics of speakers is extremely biased.

There is also a case called 'open set' identification, in which a reference model for an unknown speaker may not exist. In this case, an additional decision alternative, 'the unknown does not match any of the models,' is required. Verification can be considered a special case of the 'open set' identification mode in which the known population size is one. In either verification or identification, an additional threshold test can be applied to determine whether the match is sufficiently close to accept the decision, or if not, to ask for a new trial.

The effectiveness of speaker verification systems can be evaluated by using receiver operating characteristics (ROC) curve adopted from psychophysics. The ROC curve is obtained by assigning two probabilities, the probability of correct acceptance (1−false rejection rate) and the probability of incorrect acceptance (false acceptance rate), to the vertical and horizontal axes respectively, and varying the decision threshold (Furui, 1989). The detection error trade-off (DET) curve has recently become popular, in which false rejection and false acceptance rates are assigned to the vertical and horizontal axes respectively (Bimbot *et al.*, 2004). The error curve is usually plotted on a normal deviate scale. With this scale, a speaker recognition system whose true speaker and impostor scores are Gaussians with the same variance will result in a linear curve with a slope equal to −1.

The DET curve representation is therefore more easily readable than the ROC curve and allows for a comparison of the system's performances over a large range of operating conditions.

The equal-error rate (EER) is a commonly accepted overall measure of system performance. It corresponds to the threshold at which the false acceptance rate is equal to the false rejection rate.

Text-Dependent, Text-Independent, and Text-Prompted Methods

Speaker recognition methods can also be divided into text-dependent (fixed passwords) and text-independent (no specified passwords) methods. The former require the speaker to provide utterances of keywords or 'key sentences,' the same text being used for both training and recognition, whereas the latter do not rely on a specific text being spoken. The text-dependent methods are usually based on template/model-sequence-matching techniques in which the time axes of an input speech sample and reference templates or reference models of the registered speakers are aligned, and the similarities between them are accumulated from the beginning to the end of the utterance. Since this method can directly exploit voice individuality associated with each phoneme or syllable, it generally achieves higher recognition performance than the text-independent method.

There are several applications, such as forensic (Kunzel, 1994) and surveillance applications, in which predetermined keywords cannot be used. Moreover, human beings can recognize speakers irrespective of the content of the utterance. Therefore, text-independent methods have recently attracted more attention. Another advantage of text-independent recognition is that it can be done sequentially, until a desired significance level is reached, without the annoyance of the speaker having to repeat keywords again and again.

Both text-dependent and text-independent methods have a serious weakness. That is, these security systems can easily be circumvented, because someone can play back the recorded voice of a registered speaker uttering keywords or key sentences into the microphone and be accepted as the registered speaker. Another problem is that people often do not like text-dependent systems because they do not like to utter their identification number, such as their social security number, within the hearing of other people. To cope with these problems, some methods use a small set of words, such as digits as keywords, and each user is prompted to utter a given sequence of keywords which is randomly chosen every time the system is used (Higgins *et al.*, 1991; Rosenberg and Soong, 1987). Yet even this method is not reliable enough, since it can be circumvented with advanced electronic recording equipment that can reproduce keywords in a requested order. Therefore, a text-prompted speaker recognition method has been proposed in which password sentences are completely changed every time (See the section Text-Independent Speaker Recognition Methods below).

Text-Dependent Speaker Recognition Methods

Text-dependent speaker recognition methods can be classified into DTW (dynamic time warping) or HMM (hidden Markov model) based methods.

DTW-Based Methods

In this approach, each utterance is represented by a sequence of feature vectors, generally, short-term spectral feature vectors, and the trial-to-trial timing variation of utterances of the same text is normalized by aligning the analyzed feature vector sequence of a test utterance to the template feature vector sequence using a DTW algorithm. The overall distance between the test utterance and the template is used for the recognition decision. When multiple templates are used, distances between the test utterance and the templates are averaged and used for the decision.

HMM-Based Methods

An HMM can efficiently model the statistical variation in spectral features. Therefore, HMM-based methods have achieved significantly better recognition accuracies than DTW-based methods (Naik *et al.*, 1989).

Text-Independent Speaker Recognition Methods

In text-independent speaker recognition, generally the words or sentences used in recognition trials cannot be predicted. Since it is impossible to model or match speech events at the word or sentence level, the following three kinds of methods shown in **Figure 2** are being actively investigated (Furui, 1997).

Long-Term-Statistics-Based Methods

As text-independent features, long-term sample statistics of various spectral features, such as the mean and variance of spectral features over a series of utterances, have been used (**Figure 2A**). However, long-term spectral averages are extreme

Figure 2 Basic structures of text-independent speaker recognition methods.

condensations of the spectral characteristics of a speaker's utterances and, as such, lack the discriminating power of the sequences of short-term spectral features used as models in text-dependent methods. In one of the trials using the long-term averaged spectrum (Furui *et al.*, 1972), the effect of session-to-session variability was reduced by introducing a weighted cepstral distance measure.

Studies on using statistical dynamic features have also been carried out. Multivariate auto-regression (MAR) models have been applied to the time series of cepstral vectors to characterize speakers, and good speaker recognition results have been obtained (Montacie *et al.*, 1992; Griffin *et al.*, 1994). It was reported that the optimum order of the MAR model was 2 or 3, and that distance normalization using *a posteriori* probability was essential to obtain good results in speaker verification.

VQ-Based Methods

A set of short-term training feature vectors of a speaker can be used directly to represent the essential characteristics of that speaker. However, such a direct representation is impractical when the number of training vectors is large, since the memory and amount of computation required become prohibitively large. Therefore, attempts have been made to find efficient ways of compressing the training data using vector quantization (VQ) techniques.

In this method, VQ codebooks, consisting of a small number of representative feature vectors, are used as an efficient means of characterizing speaker-specific features (Li and Wrench, 1983; Matsui and Furui, 1990; Matsui and Furui, 1991; Rosenberg and Soong, 1987). In the recognition stage, an input utterance is vector-quantized by using the codebook

of each reference speaker; the VQ distortion accumulated over the entire input utterance is used for making the recognition determination (Figure 2B).

Matsui and Furui (1990, 1991) tried a method using a VQ-codebook for long feature vectors consisting of instantaneous and transitional features calculated for both cepstral coefficients and fundamental frequency. Since the fundamental frequency cannot be extracted from unvoiced speech, there are two separate codebooks for voiced and unvoiced speech for each speaker. A new distance measure was introduced to take into account intraspeaker and interspeaker variability and to deal with the problem of outlier in the distribution of feature vectors. The outlier vectors correspond to intersession spectral variation and to the difference between phonetic content of the training texts and the test utterances. It was confirmed that, although the fundamental frequency achieved only a low recognition rate by itself, the recognition accuracy was greatly improved by combining the fundamental frequency with spectral envelope features.

In contrast with the memoryless VQ-based method, nonmemoryless source coding algorithms have also been studied using a segment (matrix) quantization technique (Juang and Soong, 1990). The advantage of a segment quantization codebook over a VQ codebook representation is its characterization of the sequential nature of speech events. Higgins and Wohlford (1986) proposed a segment modeling procedure for constructing a set of representative time normalized segments, which they called 'filler templates.' The procedure, a combination of K-means clustering and dynamic programming time alignment, provided a means for handling temporal variation.

Ergodic-HMM-Based Methods

The basic structure is the same as the VQ-based method, but in this method an ergodic HMM is used instead of a VQ codebook. Over a long timescale, the temporal variation in speech signal parameters is represented by stochastic Markovian transitions between states. Poritz (1982) proposed using a five-state ergodic HMM (i.e., all possible transitions between states are allowed) to classify speech segments into one of the broad phonetic categories corresponding to the HMM states. A linear predictive HMM was adopted to characterize the output probability function. He characterized the automatically obtained categories as strong voicing, silence, nasal/liquid, stop burst/post silence, and frication.

Gauvain *et al.* (1995) investigated a statistical modeling approach, where each speaker was viewed as a source of phonemes, modeled by a fully connected Markov chain. Maximum *a posteriori* (MAP) estimation was used to generate speaker-specific models from a set of speaker-independent seed models. The lexical and syntactic structures of the language were approximated by local phonotactic constraints. The unknown speech is recognized by all of the speakers' models in parallel, and the hypothesized identity is that associated with the model set having the highest likelihood. Since phonemes and speakers are simultaneously recognized by using speaker-specific Markov chains, this method can be considered as an extension of the ergodic-HMM-based method.

Matsui and Furui (1992) compared the VQ-based method with the discrete/continuous ergodic HMM-based method, particularly from the viewpoint of robustness against utterance variations. They found that the continuous ergodic HMM method is far superior to the discrete ergodic HMM method and that the continuous ergodic HMM method is as robust as the VQ-based method when enough training data is available. However, when little data is available, the VQ-based method is more robust than the continuous HMM method. They investigated speaker identification rates using the continuous HMM as a function of the number of states and mixtures. It was shown that the speaker recognition rates were strongly correlated with the total number of mixtures, irrespective of the number of states. This finding means that using information on transitions between different states is ineffective for text-independent speaker recognition.

Rose and Reynolds (1990) investigated a technique based on maximum likelihood estimation of a Gaussian mixture model (GMM) representation of speaker identity. This method corresponds to the single-state continuous ergodic HMM. Gaussian mixtures are noted for their robustness as a parametric model and for their ability to form smooth estimates of rather arbitrary underlying densities. The VQ-based method can be regarded as a special (degenerate) case of a single-state HMM with a distortion measure being used as the observation probability.

Speech-Recognition-Based Methods

The VQ- and HMM-based methods can be regarded as methods that use phoneme-class-dependent speaker characteristics contained in short-term spectral features through implicit phoneme-class recognition.

In other words, phoneme-classes and speakers are simultaneously recognized in these methods. On the other hand, in the speech-recognition-based methods (Figure 2C), phonemes or phoneme-classes are explicitly recognized, and then each phoneme(-class) segment in the input speech is compared with speaker models or templates corresponding to that phoneme (-class).

Savic and Gupta (1990) used a five-state ergodic linear predictive HMM for broad phonetic categorization. In their method, after frames that belong to particular phonetic categories have been identified, feature selection is performed. In the training phase, reference templates are generated and verification thresholds are computed for each phonetic category. In the verification phase, after phonetic categorization, a comparison with the reference template for each particular category provides a verification score for that category. The final verification score is a weighted linear combination of the scores for each category. The weights are chosen to reflect the effectiveness of particular categories of phonemes in discriminating between speakers and are adjusted to maximize the verification performance. Experimental results showed that verification accuracy can be considerably improved by this category-dependent weighted linear combination method.

Rosenberg *et al.* (1991) tested a speaker verification system using four-digit phrases in actual field conditions, with a banking application input speech that was segmented into individual digits using a speaker-independent HMM. The frames within the word boundaries for a digit were compared with the corresponding speaker-specific HMM digit model and the Viterbi likelihood score was computed. This computation was done for each of the digits making up the input utterance. The verification score was defined to be the average normalized log-likelihood score over all the digits in the utterance.

Newman *et al.* (1996) used a large vocabulary speech recognition system for speaker verification. A set of speaker-independent phoneme models were adapted to each speaker. Speaker verification consisted of two stages. First, speaker-independent speech recognition was run on each of the test utterances to obtain phoneme segmentation. In the second stage, the segments were scored against the adapted models for a particular target speaker. The scores were normalized by those with speaker-independent models. The system was evaluated using the 1995 NIST-administered speaker verification database, which consists of data taken from the Switchboard corpus. The results showed that this method could not out-perform Gaussian mixture models.

Text-Prompted Speaker Recognition

In this method, key sentences are completely changed every time (Matsui and Furui, 1993; Matsui and Furui, 1994b). The system accepts the input utterance only when it determines that the registered speaker uttered the prompted sentence. Because the vocabulary is unlimited, prospective impostors cannot know in advance the sentence they will be prompted to say. This method not only accurately recognizes speakers, but can also reject an utterance whose text differs from the prompted text, even if it is uttered by a registered speaker. Thus, a recorded and played-back voice can be correctly rejected.

This method uses speaker-specific phoneme models as basic acoustic units. One of the major issues in this method is how to properly create these speaker-specific phoneme models when using training utterances of a limited size. The phoneme models are represented by Gaussian-mixture continuous HMMs or tied-mixture HMMs, and they are made by adapting speaker-independent phoneme models to each speaker's voice.

In the recognition stage, the system concatenates the phoneme models of each registered speaker to create a sentence HMM, according to the prompted text. Then the likelihood of input speech against the sentence model is calculated and used for the speaker verification determination.

Normalization and Adaptation Techniques

How can we normalize intraspeaker variation of likelihood (similarity) values in speaker verification? The most significant factor affecting automatic speaker recognition performance is variation in signal characteristics from trial to trial (intersession variability or variability over time). Variations arise from the speaker him/herself, from differences in recording and transmission conditions, and from noise. Speakers cannot repeat an utterance precisely the same way from trial to trial. It is well known that samples of the same utterance recorded in one session are much more highly correlated than tokens recorded in separate sessions. There are also long term trends in voices (Furui *et al.*, 1972; Furui, 1974).

It is important for speaker recognition systems to accommodate these variations. Adaptation of the reference model as well as the verification threshold for each speaker is indispensable to maintain a high recognition accuracy for a long period. In order to compensate for the variations, two types of normalization techniques have been tried – one in the parameter domain, and the other in the distance/similarity

domain. The latter technique uses the likelihood ratio or *a posteriori* probability. To adapt HMMs for noisy conditions, various techniques including the HMM composition (PMC: parallel model combination) method, have proved successful.

Parameter-Domain Normalization

As one typical normalization technique in the parameter domain, spectral equalization, the so-called 'blind equalization' method, has been confirmed to be effective in reducing linear channel effects and long-term spectral variation (Atal, 1974; Furui, 1981). This method is especially effective for text-dependent speaker recognition applications using sufficiently long utterances. In this method, cepstral coefficients are averaged over the duration of an entire utterance, and the averaged values are subtracted from the cepstral coefficients of each frame (CMS; cepstral mean subtraction). This method can compensate fairly well for additive variation in the log spectral domain. However, it unavoidably removes some text-dependent and speaker-specific features, so it is inappropriate for short utterances in speaker recognition applications. It was shown that time derivatives of cepstral coefficients (delta-cepstral coefficients) are resistant to linear channel mismatch between training and testing (Furui, 1981; Soong and Rosenberg, 1988).

Likelihood Normalization

Higgins *et al.* (1991) proposed a normalization method for distance (similarity or likelihood) values that uses a likelihood ratio. The likelihood ratio is the ratio of the conditional probability of the observed measurements of the utterance, given the claimed identity is correct, to the conditional probability of the observed measurements, given the speaker is an impostor (normalization term). Generally, a log-likelihood ratio indicates a valid claim, whereas a negative value indicates an imposter. The likelihood ratio normalization approximates optimal scoring in Bayes' sense.

This normalization method is, however, unrealistic because conditional probabilities must be calculated for all the reference speakers, which requires large computational cost. Therefore, a set of speakers, 'cohort speakers,' who are representative of the population distribution near the claimed speaker has been chosen for calculating the normalization term. Another way of choosing the cohort speaker set is to use speakers who are typical of the general population. Reynolds (1994) reported that a randomly selected, gender-balanced background speaker population outperformed a population near the claimed speaker.

Matsui and Furui (1993, 1994a) proposed a normalization method based on *a posteriori* probability. The difference between the normalization method based on the likelihood ratio and that based on *a posteriori* probability is whether or not the claimed speaker is included in the impostor speaker set for normalization; the cohort speaker set in the likelihood-ratio-based method does not include the claimed speaker, whereas the normalization term for the *a posteriori*-probability-based method is calculated by using a set of speakers, including the claimed speaker. Experimental results indicate that both normalization methods almost equally improve speaker separability and reduce the need for speaker-dependent or text-dependent thresholding, compared with scoring using only the model of the claimed speaker (Matsui and Furui, 1994a; Rosenberg, 1992).

Carey and Parris (1992) proposed a method in which the normalization term is approximated by the likelihood for a world model representing the population in general. This method has an advantage that the computational cost for calculating the normalization term is much smaller than the original method since it does not need to sum the likelihood values for cohort speakers. Matsui and Furui (1994a) proposed a method based on tied-mixture HMMs in which the world model is made as a pooled mixture model representing the parameter distribution for all the registered speakers. The use of a single background model for calculating the normalization term has become the predominant approach used in speaker verification systems.

Since these normalization methods neglect absolute deviation between the claimed speaker's model and the input speech, they cannot differentiate highly dissimilar speakers. Higgins *et al.* (1991) reported that a multilayer network decision algorithm makes effective use of the relative and absolute scores obtained from the matching algorithm.

A family of normalization techniques has recently been proposed, in which the scores are normalized by subtracting the mean and then dividing by standard deviation, both terms having been estimated from the (pseudo)imposter score distribution. Different possibilities are available for computing the imposter score distribution: Znorm, Hnorm, Tnorm, Htnorm, Cnorm, and Dnorm (Bimbot *et al.*, 2004). The state-of-the-art text-independent speaker verification techniques associate one or several parameterization level normalization (CMS, feature variance normalization, feature warping, etc.) with a world model normalization and one or several score normalizations.

HMM Adaptation for Noisy Conditions

Increasing the robustness of speaker recognition techniques against noisy speech or speech distorted by a telephone is a crucial issue in real applications. Rose *et al.* (1994) applied the HMM composition (PMC) method (Gales and Young, 1993; Martin *et al.*, 1993) to speaker identification under noisy conditions. The HMM composition is a technique to combine a clean speech HMM and a background noise HMM to create a noise-added speech HMM. In order to cope with the problem of the variation of the signal-to-noise ratio (SNR), Matsui and Furui (1996b) proposed a method in which several noise-added HMMs with various SNRs were created, and the HMM that had the highest likelihood value for the input speech was selected. A speaker decision was made using the likelihood value corresponding to the selected model. Experimental application of this method to text-independent speaker identification and verification in various kinds of noisy environments demonstrated considerable improvement in speaker recognition.

Updating Models and *a Priori* Threshold for Speaker Verification

How to update speaker models to cope with the gradual changes in people's voices is an important issue. Since we cannot ask every user to utter many utterances at many different sessions in real situations, it is necessary to build each speaker model based on a small amount of data collected in a few sessions, and then the model must be updated using speech data collected when the system is used.

How to set the *a priori* decision threshold for speaker verification is another important issue. In most laboratory speaker recognition experiments, the threshold is set *a posteriori* so that the equal error rate (EER) is achieved. Since the threshold cannot be set *a posteriori* in real situations, we have to have practical ways to set the threshold before verification. It must be set according to the relative importance of the two errors, which depends on the application.

These two problems are intrinsically related each other. Furui (1981) proposed methods for updating reference templates and the threshold in DTW-based speaker verification. An optimum threshold was estimated based on the distribution of overall distances between each speaker's reference template and a set of utterances of other speakers (interspeaker distances). The interspeaker distance distribution was approximated by a normal distribution, and the threshold was calculated by the linear combination of its mean value and standard deviation. The intraspeaker distance distribution was not taken into account in the calculation, mainly because it is difficult to obtain stable estimates of the intraspeaker distance distribution from small numbers of training utterances. The reference template for each speaker was updated by averaging new utterances and the present template after time registration. Matsui and Furui (1996a) extended these methods and applied them to text-independent and text-prompted speaker verification using HMMs.

High-Level Speaker Recognition

Recently, high-level features such as word idiolect, pronunciation, phone usage, prosody, etc., have been successfully used in text-independent speaker verification. Typically, high-level-feature recognition systems produce a sequence of symbols from the acoustic signal and then perform recognition using the frequency and co-occurrence of symbols. In Doddington's idiolect work (2001), word unigrams and bigrams from manually transcribed conversations were used to characterize a particular speaker in a traditional target/background likelihood ratio framework. Campbell *et al.* (2004) proposed the use of support vector machines for performing the speaker verification task based on phone and word sequences obtained using phone recognizers. The benefit of these features was demonstrated in the 'NIST extended data' task for speaker verification; with enough conversational data, a recognition system can become 'familiar' with a speaker and achieve excellent accuracy. The corpus was a combination of phases 2 and 3 of the Switchboard–2 corpora. Each training utterance in the corpus consisted of a conversation side that was nominally of length 5 minutes (approximately 2.5 minutes of speech) recorded over a landline telephone. Speaker models were trained using 1–16 conversation sides. These methods need utterances of at least several minutes long, much longer than those used in conventional speaker recognition methods.

Relationship with Other Speech Technology

Speaker characterization techniques are related to research on improving speech recognition accuracy by speaker adaptation (Furui, 1991), improving synthesized speech quality by adding the natural characteristics of voice individuality, and converting synthesized voice individuality from one speaker to another. Studies on automatically extracting the speech periods of each person separately from a dialogue/conversation/meeting involving more than two

people have appeared as an extension of speaker recognition technology (Gish *et al.*, 1991; Siu *et al.*, 1992; Wilcox *et al.*, 1994). Increasingly, speaker segmentation and clustering techniques are being used to aid adapting speech recognizers and for supplying metadata for audio indexing and searching.

Specific Language Impairment

G Conti-Ramsden and N Botting, University of Manchester, Manchester, UK

© 2006 Elsevier Ltd. All rights reserved.

Introduction

Since research on specific language impairment (SLI) started a few decades ago it has become evident that although the majority of children appear to learn language quickly and effortlessly, there are some for whom this is not the case. SLI is characterized by the early onset of language difficulties, which then persist and become 'out of line' with age and cognitive development. Children with SLI have problems from the outset of the language-learning process. Instead of reaching early developmental milestones on schedule and then encountering specific difficulties (e.g., in grammatical morphology or entering a period of extremely slow development), these children are in fact slow from the beginning, i.e., all children with SLI come from the population of late talkers (Conti-Ramsden, 2003). It is a hallmark of SLI that these children are late in acquiring their first words and their first word combinations and thus, difficulties and protracted development are present from the emergence of language.

Prevalence and Diagnosis

SLI is currently diagnosed using exclusionary criteria. That is, language impairment must be present without obvious cause such as nonverbal learning difficulties (although see later), hearing impairment, frank neurological disability, or autism. It is a developmental disorder and as mentioned previously language difficulties must be evident at a young age. Interestingly, it is a relatively common disorder as it is thought to affect between 5% and 7% of the population (Tomblin *et al.*, 1992) with boys being more affected than girls at a ratio of 2:1 (Bishop, 1997).

There are a number of different definitions of what constitutes a language impairment in practice at any one time. Tomblin and colleagues concluded that language scores falling below 1.25 SD from the normative mean (approx. 10th centile) was a 'gold standard' for language impairment (Tomblin *et al.*, 1996). Often, however, academics and clinicians use 1 SD as a threshold. Children are usually required to fall below the normal range on at least one test of language. The level of nonverbal IQ needed for a diagnosis of SLI is more controversial. While many researchers favor scores of 85 points (1 SD) or higher, UK educational practice as well as DSM-IV (American Psychiatric Association, 1994) deems a score above 70 (2 SD) rather than above 85 to indicate a lack of generalized learning difficulty. There have also been questions raised regarding the use of thresholds (for example, do children with IQs of 86 and language scores of 84 really have SLI?) and also conversely with discrepancy or difference measures where children must have an IQ–language difference of a certain magnitude (Bishop, 1997). Recent studies have also questioned the relevance of nonverbal IQ in the diagnosis of SLI, both because IQ in children with SLI appears to decline over time (Botting, forthcoming) and because clinically those with higher and lower IQs might have identical needs (Bishop, 1997).

Despite the fact that SLI is the current term used in research and education, psychiatric diagnostic manuals use different terminology. DSM-IV (American Psychiatric Association, 1994), for example, uses the term 'developmental language disorder' and ICD 10 (World Health Organization, 1992) the terms 'expressive developmental language disorder' and 'receptive developmental language disorder' (see the section 'SLI Is Not Homogenous' below for a description of expressive/receptive disorders).

Characteristics of Children with SLI

Children with SLI are late talkers but not all late talkers are children with SLI. There are many children who are referred to as 'late talkers' who subsequently develop age-appropriate language skills and these children are not thought to have SLI (although later complex language and literacy skills might be affected; see e.g., Rescorla, 2002). Equally, children who have learned language and then suddenly lose these skills are more likely to have an acquired language disorder caused by trauma, illness, or other psychiatric conditions. Unlike children with autism, children with SLI do not show difficulties with social relationships at a young age, usually have no difficulty on theory of mind or perspective-taking tasks and do not have rigid or obsessive behaviors. Thus their nonverbal communication tends to be notably better than their actual language.

A number of the language difficulties seen in SLI appear to be syntactic in nature, and the majority of children with SLI learning English seem to have particular difficulty with verb morphology. Thus failure to mark tense accurately, make appropriate subject–verb agreement, and use of auxiliaries are all areas of difficulty for those children with SLI learning English. Figure 1 shows transcripts of real dialogues between mothers and their three- and four-year-old children

1. Pronoun case error with finite form
Mother: "I thought she was at school."
Child: "Er, her* is!" [error: her = she]
Mother: "she is."
Child: "she is." [imitating]
Use of an accusative pronoun (her) for the subject of a finite third person verb form (is). The adult target is a nominative case pronoun (she).

2. Missing auxiliary
"I ∅* staying there right here." [error: ∅ = am]
Omission of the auxiliary form "am" inflected for agreement (first person singular) and tense (present).

3. Missing copula
"Aah, ∅* that a little boat?" [error: ∅ = is]
Omission of the copula form "is" inflected for agreement (third person singular) and tense (present).

4. Missing third person-*s*
"That go* this way." [error: go = goes]
Omission of the third person present marker-s. The target form is "goes" instead of the uninflected form "go."

5. Missing infinitival particle *to*
"Want ∅* take it out." [error: ∅ = to]
Omission of the infinitival particle *to*. The target is "I want to take it out."

6. Missing regular past tense-*ed* inflection
Child: "And he empty* the bin." [error: empty = emptied]
Mother: "Did he?"
Use of an uninflected form (empty) instead of the regular past tense form (emptied).

7. Past tense overregularization
Mother: "Then what did Mommy do?"
Child: "Catched* it." [error: catched = caught]
Use of an overregularised form (catched) instead of the target irregular past tense form (caught).

Figure 1 Examples of syntactic errors.

with SLI that include typical examples of these type of errors.

However, many children also have semantic difficulties, either with word finding (Dockrell *et al.*, 2001) or understanding meanings and inferences (Botting and Adams, forthcoming). Indeed, these other areas of difficulty might contribute to the syntactic impairments often seen. Recently, phonological short-term memory and nonword repetition tasks (in which novel words are repeated immediately after presentation – see below) have been highlighted as possible markers for SLI because a large proportion of children with SLI show very poor ability in this area (Gathercole and Baddeley, 1990; Bishop *et al.*, 1995).

SLI is not Homogenous

It is universally recognized that SLI is not a homogenous condition but is an umbrella term for a number of different clinical types. A number of different classification systems have been devised (Conti-Ramsden and Botting, 1999; Rapin and Allen, 1987). However, the enduring categories used appear to be those referring to the terms 'expressive (or production/output) difficulties' and 'receptive (or comprehension/understanding) difficulties.' There is general acceptance that the majority of children with SLI have expressive difficulties but that these can be present in isolation or combined with receptive difficulties. Recently, a third subtype has received much attention. These are children in whom pragmatic language difficulties, i.e., their social use of language, are the most prominent disability. These children are currently referred to as having pragmatic language impairment. They would previously have been described as having semantic–pragmatic disorder, but this term is less used following research and clinical opinion that suggested semantic difficulties were no more common in this group than in other subtypes of SLI (Bishop, 1998).

Theories about the Causes of SLI

The last few decades have witnessed a shift in the theory of the possible causes of SLI. In parallel with those theories governing normal language acquisition, this shift has been away from environmental causes and toward a more genetic and biological point of view. It has been noted that SLI often runs in families (e.g., Tallal *et al.*, 1989) and the latest investigations are attempting to isolate this apparent heritability. A large body of evidence is being gathered that supports the role of genes in the etiology of SLI although it is acknowledged that the genetic basis of the disorder is likely to be complex (Bishop *et al.*, 1995). It is also acknowledged that there is likely to be an interplay between environmental and genetic/biological factors in the expression of SLI.

Over the years a number of theories have been developed to account for possible causes of SLI. Each of these theories has its distinct features but most can be classified under two major headings: processing theories versus linguistic theories. In general, linguistic theories of SLI assume that language and language structures are innate and independent, sometimes with a grammar 'module' being a hardwired part of neurodevelopment. In contrast, processing theories of SLI take a more interactionist stance, in which language develops dynamically in interaction with external stimuli, and in relation to other systems such as cognition.

Linguistic theories of SLI are inevitably derived from Chomskyan theory, whereby SLI is proposed to manifest deficits in, immaturity of, or the absence

of innate grammatical modules. Thus, it is thought that children with SLI develop selective impairments that affect specific components of universal grammar. And to some extent, this appears to be the case. Children with SLI appear to have problems with morphosyntax, thus omitting syntactic morphemes at a rate greater than their mean length of utterance would predict. Theories have tried to specify the nature of this problem by proposing missing features (Gopnick, 1997), problems with tense and more recently agreement and tense (Wexler *et al*., 1998), and problems with agreement only (Clahsen, 1989). Within this theoretical framework, Van der Lely (1994) has suggested that although morphosyntax appears to be particularly prone to impairment, children with SLI have difficulties with a broader range of syntactic structures and relations, particularly the interpretation of thematic roles.

The above theories have been challenged by processing theories of SLI. This perspective suggests that the observed deficits in grammar are the result of difficulties with processing abilities. Furthermore, it underlines the fact that children with SLI appear to have difficulties beyond grammatical morphemes and grammatical relations. Children with SLI have difficulties acquiring words in the first instance. They also have difficulties formulating sentences and retelling stories. Theories have varied in their specific approaches and explanations. It has been suggested that children with SLI have phonological short-term memory deficits (Gathercole and Baddeley, 1990), more general working memory deficits (Montgomery, 2000), an overall slow processing system (Kail, 1994), and auditory perception impairments (Tallal *et al*., 1985).

At the same time, there has been a line of research challenging the 'specific' nature of SLI. Interestingly, a number of studies have identified nonverbal difficulties in children with SLI such as mental imagery and hypothesis testing (see Leonard, 1998 for a review). Interest in the application of computer models to the understanding of language learning and disorders suggests that the language difficulty is not isolated in development but may affect and be affected by other systems (Thomas and Karmiloff-Smith, 2002). Processing theories are consistent with a wider notion of SLI (without specificity to language only) while linguistic theories find this type of evidence more difficult to reconcile with their approach.

The Development and Prognosis of SLI

It used to be thought that SLI was a short-term, preschool delay in language learning. Although this may be true for a proportion of children experiencing language delay, recent follow-up studies have shown that language difficulties can persist well into adolescence and even adulthood (Clegg *et al*., forthcoming; Stothard *et al*., 1998). Longitudinal studies have also suggested that the language profiles of individual children can change over time (Conti-Ramsden and Botting, 1999) as well as their nonverbal functioning (Botting, forthcoming). Persistent language impairment has been associated with poorer reading and school progress (Snowling *et al*., 2001) as well as with social and psychiatric difficulties (Beitchman *et al*., 2001; Conti-Ramsden and Botting, 2004). Research into the lifelong effects of SLI is only just beginning and the findings so far have not been consistent. It appears, nevertheless, that it is possible for people with SLI to have a good quality of life, find employment, and establish long-term relationships. Often language difficulties are not noticeable because of improvement, strategy use, and the accommodation of behavior to get around the difficulty (i.e., not putting oneself into situations where language impairment becomes obvious).

Specificity

D Farkas, University of Santa Cruz, Santa Cruz, CA, USA

© 2006 Elsevier Ltd. All rights reserved.

The notion of specificity entered contemporary linguistics through the door of philosophy of language and semantics. It has played an increasingly important role in semantic theory as well as in work on the syntax–semantics and morphology–semantics interfaces. For the semanticist, specificity is interesting because of its relevance to theories of reference; for the syntactician and morphologist, specificity is relevant to phenomena such as differential object marking (clitic doubling as well as special case markings), weak islands, and multiple wh-questions.

Specificity was brought onto the scene in order to make subtler distinctions within the class of noun phrases (NPs) when the definite/indefinite distinction proved insufficient for characterizing the rich semantic, pragmatic, syntactic, and morphological phenomena that drive the drawing of boundaries within the realm of NP semantics. Farkas (1994, 2002a) distinguished three subtypes of specificity: scopal, partitive, and epistemic. Below I characterize each, and then briefly discuss why they have to be distinguished and what a common denominator among them might be.

Scopal specificity concerns the question of whether an NP is interpreted within the scope of a quantifier, a negation, or an intensional predicate (nonspecific) or outside it (specific). The referent of a scopally nonspecific NP varies in a way that is determined by the operator in whose scope the NP finds itself.

(1) John wants to marry **a Norwegian girl**.

(2) He met **her** last year.

In (1), under the wide scope reading of the boldface NP, its referent is constant across the alternatives introduced by *wants;* under the narrow scope reading, it is not. Example (2) is an appropriate continuation of (1) only under the former interpretation. The particular properties of a scopally nonspecific NP depend on the operator in whose scope the NP is interpreted. Thus, the interpretation of the wide scope reading of the indefinite NP in (3) is the same as the wide scope reading of the indefinite in (1); under its narrow scope reading, however, there is now covariation between students in the class and languages spoken.

(3) Every student in this class speaks **a foreign language**.

The languages and the students who speak them inhabit the same 'world' in (3), whereas in (1), under the narrow scope (scopally nonspecific) reading of the indefinite, the question of where the (relevant) Norwegian girl exists is more complex.

Narrow scope relative to negation, exemplified in (4), is different from both these cases.

(4) John hasn't seen **a/any Norwegian girl**.

In many languages, among them English, indefinite NPs within the immediate scope of negation are specially marked, in English by the determiner *any*. The fate of NPs within the immediate scope of negation is part of the web of phenomena studied under the rubric of negative polarity items (NPI).

Scopal specificity, under its present characterization, is a relative notion: An NP may be within the scope of some operator *O* (and therefore scopally nonspecific relative to *O*) but outside the scope of some other operator *O'* (and therefore scopally specific relative to *O'*). This is indeed what we find in cases of intermediate scope, discussed in Fodor and Sag (1982) and Farkas (1981), and exemplified in (5).

(5) Every professor gave an A to every student who translated **a difficult poem by Pindar**.

Here the indefinite *a difficult poem by Pindar* may be interpreted as scopally nonspecific relative to *every professor* but as scopally specific relative to *every student*. Under this interpretation, for every professor there was a particular poem such that that professor gave an A to every student who translated that poem. Intermediate scope interpretations of sentences such as (5) have played an important role in the discussion of the proper treatment of NP scope.

The term nonspecific NP is sometimes used for a class of NPs that has a special scopal property, namely that of having to be interpreted together with the predicate that the NP in question is an argument of. These NPs have necessarily narrow scope relative to any operator that scopes over their predicate. Carlson (1977) showed that existential bare plurals in English are examples of such NPs. Existential bare plural NPs are exemplified in (6). Their scopal inertness (i.e., the fact that they always scope with their predicate and thus do not participate in scopal ambiguities in the presence of other operators) is exemplified in (7) and (8), which can only be interpreted with the bare plural within the scope of negation and the universal, respectively.

(6) John saw **spots on the floor**.

(7) John didn't see **spots on the floor**.

(8) Everybody saw **spots on the floor.**

Scopal specificity as discussed here is independent of definiteness because, as shown in (9), a definite NP may be interpreted within the scope of an operator and therefore may be scopally nonspecific:

(9) Every student invited **the girl sitting to his right**.

There is, however, a marked tendency for definite NPs to be interpreted as having widest scope, and such NPs are never scopally inert.

Partitive specificity (Enç, 1991) concerns the question of whether an indefinite NP refers within a discourse-familiar group (specific) or not (nonspecific). *Some ghosts* in (11) (Enç, 1991) is partitive-specific, whereas in (10) it is not:

(10) There are **some ghosts** in this house.

(11) **Some ghosts** live in the attic; others, in the basement.

The crucial property that makes the indefinite in (11) partitive-specific is that its referent is a subset of the referent of the indefinite in (10). In this example, partitivity is not marked morphologically: The two indefinites are formally identical. In the case in which (10) precedes the utterance of (11), the partitivity of the indefinite in (11) arises contextually. When (11) is uttered out of context, the indefinite is interpreted just as the one in (10). There are, however, NPs called overt partitives that **must** receive a partitive-specific interpretation, such as the boldface NP in (12).

(12) **Some of the ghosts** live in the attic; others, in the basement.

This example is used felicitously only if uttered in a context that has established the existence of some ghosts that can provide the set, a subset of which is referred to by the partitive in (12). Finally, note that partitive specificity is incompatible with definiteness. Changing *some ghosts* to *the ghosts* in (11) enforces a nonpartitive interpretation; the definite has to refer to all the ghosts introduced in (10).

Epistemic specificity (Fodor and Sag, 1982) concerns the question of whether the speaker has an intended referent in mind (specific) or not (nonspecific). The former interpretation is forced on the indefinite in (13) by the continuation in (14); the latter interpretation is forced by the continuation in (15):

(13) **A student** cheated.

(14) **He** is John.

(15) We don't know who **he** was.

The referent of epistemically specific NPs is constant across the speaker's (or addressee's) epistemic alternatives; that of epistemically nonspecific ones is not. In the case of the former interpretation of the indefinite in (13), the speaker has a particular student in mind, whereas, in the case of the latter, she does not. Whether an indefinite NP receives an epistemically specific interpretation or not is greatly influenced by the context in which the NP occurs. Note that, epistemic nonspecificity is compatible with definiteness. Thus, the boldface definite in (16) is most likely to be interpreted as epistemically nonspecific:

(16) **The last person to leave the room** will switch off the lights.

Scopal matters as well as issues connected to overt partitive specificity have been assumed to fall within the realm of semantics proper. Whether epistemic specificity is a matter of semantics narrowly construed, and thus enters into determining truth conditions, or whether it should be relegated to the realm of pragmatics is a controversial issue. Ludlow and Neale (1991) argued for a pragmatic approach, contra Fodor and Sag, claiming that the utterance of (13), under an epistemically specific interpretation, would be judged as true even if it turned out that there was indeed a student who had cheated but that the cheater was not the student the speaker had in mind.

A notion of specificity closely related to epistemic specificity is involved in characterizing *a certain* indefinites, exemplified in (17).

(17) **A certain student** cheated on the exam.

Such specific indefinites are, intuitively, antifree-choice items, signaling that there is a particular intended choice of value, even though neither speaker nor addressee must necessarily be in a position to identify it at the time of the speech act. In Farkas (2002b), it is argued that this type of specificity is characterized by the existence of the possibility of the unique identification of the intended referent.

I turn now to the reasons for keeping these various subspecies of specificity apart. Fodor and Sag note that, because scopal interaction is irrelevant to (13), epistemic specificity must be independent of scope. The independence of partitivity from scopal and epistemic specificity is shown by (18) and (19).

(18) John wants to marry **one of Steve's sisters** (he doesn't care which).

(19) **One of Steve's sisters** cheated (we have to find out which).

The overt partitive-specific NP in (18) may be interpreted within the scope of the intensional predicate *wants*, and the continuation in parentheses forces this scopally nonspecific interpretation. The overt partitive

in (19) may be interpreted as epistemically nonspecific, an interpretation that is forced by the continuation in parentheses. Thus, partitive specificity does not entail either scopal or epistemic specificity.

In (20), fashioned after a famous example due to Geach, the indefinite may be scopally nonspecific relative to the predicate *believes* but epistemically specific as far as Cob is concerned:

(20) Cob believes that **a witch** ate his tomatoes. He believes **her** name is Martha..

The referent of *a witch* is chosen from among the entities that populate Cob's version of reality, rather than the speaker's, making it scopally nonspecific. Cob may, however, have a particular witch in mind, whose identity is constant throughout his epistemic alternatives, making the NP epistemically specific. This example shows that epistemic specificity does not entail scopal specificity.

Distinguishing these various versions of nonspecificity is easier than finding what they have in common. A possible common denominator underlying these three notions is that of stability/instability of reference. The differences among the three notions arise because the parameters against which stability is measured are different in each case. Thus, scopal specificity concerns stability/instability relative to parameters introduced by the scope-taking operator. In the case of scope relative to an intensional predicate such as *want*, for instance, scopally specific NPs are stable as far as the alternatives introduced by the operator are concerned, whereas the reference of scopally nonspecific NPs varies relative to these alternatives. Similarly, in the case of scope relative to a universal quantifier, scopally specific NPs have a stable reference relative to the variable bound by the universal, whereas scopally nonspecific NPs covary with it.

Epistemic specificity concerns stability/instability across a cognitive agent's epistemic alternatives. If an NP is epistemically specific relative to a particular cognitive agent, its value is constant relative to the alternatives that the agent considers to be viable candidates for reality. Under an epistemically specific interpretation of *a student* in (13), for instance, the speaker is the relevant cognitive agent and, in all the alternatives she considers possible, the identity of the cheater is the same. Under an epistemically nonspecific interpretation of the NP, all the speaker is committed to is the existence of a cheater, and therefore the referent of the NP is not constant across the epistemic alternatives that she is publicly committed to. In the case of partitives, the stability/instability of reference concerns the freedom we have in choosing possible values. Partitive specificity involves the necessary contextual narrowing of possible value choices to a subset of a previously introduced set, whereas nonpartitive indefinites do not involve such a restriction. The restriction involved in partitivity is akin to that characterizing definiteness, having led to the postulation of partitives as a special, intermediate rung on the scale from indefinites to definites.

Speech

J Laver, Queen Margaret University College, Edinburgh, UK

© 2006 Elsevier Ltd. All rights reserved.

This article aims to offer a panoramic view of the topic of speech, as a complement to the general articles on language in this encyclopedia (for more specific discussion of individual sectors in this very broad area, *see* **Phonetics: Overview**; **Phonology: Overview**; **Psycholinguistics: Overview** and **Applied Linguistics: Overview and History**). Emphasis is given here to areas of speech that are less directly concerned with general linguistic theory as such. It is immediately apparent that no single discipline can hope to offer a complete account of all the different facets of speech that are of potential scientific interest. Within the main domain of this encyclopedia, the sister sciences of phonetics and linguistics obviously lie at the core of the study of spoken language. However, whereas spoken language is certainly a pre-eminent focus of phonetics and linguistics, those subjects by no means exhaust the study of speech. Many other disciplines exist for which speech is a partial interest, and each of these brings its own unique perspective to the overall study of speech. In fact, speech as a subject is at the intersection of well over 50 different disciplines, each with a professional contribution to make to its study. A fuller understanding of the nature of speech may therefore emerge from considering this wider range of disciplines – including, but also well beyond the linguistic sciences alone – that can illuminate different facets of speech.

Leaving aside the universal utilities of mathematics, logic, philosophy, statistics, cybernetics, and mechanics, which, though contributing pervasively useful concepts have little that is unique to say about speech as such, there are three groups of sciences that have a more specific relevance. These are the life sciences, the social sciences, and the physical sciences. The life sciences include at least 14 disciplines with a degree of professional interest in speech, its development, and its disorders. These are anatomy, audiology, biology, dentistry, genetics, medicine, neurology, otorhinolaryngology, pathology, phoniatrics, physiology, psychiatry, speech/language/hearing pathology, and speech/language/hearing therapy.

The social sciences contribute some 30 disciplines that draw some of their data, even if sometimes rather indirectly, from speech. These are applied linguistics, anthropology, communication, comparative linguistics, conversational analysis, descriptive linguistics, dialectology, discourse analysis, historical linguistics, historical phonology, languages, language learning, linguistics, literary theory, music, nonverbal communication, oratory, paralinguistics, philology, phonetics, phonology, poetics, psycholinguistics, psychology, rhetoric, semiotics, sign language, sociolinguistics, sociology, and writing systems (including printing and notation). Some readers may be surprised to see the inclusion of writing systems within speech as a subject. The rationale for this (and of course an opposing view is not untenable) is that writing ultimately derives, historically and semiotically, from spoken language.

The physical and engineering sciences are also well represented in the spectrum of disciplines that take a direct interest in speech. Fifteen such disciplines include acoustics, aerodynamics, artificial intelligence, computing, electrical engineering, electronic engineering, experimental phonetics, forensic phonetics, human/computer interaction, natural language processing, physics, signal processing, speech science, speech technology, and telecommunications engineering.

Note that a superordinate/subordinate relationship may seem to obtain between some of the larger disciplines mentioned in the three groups, such as medicine as an overarching subject and anatomy, physiology, neurology, and pathology as component disciplines. The view taken here is that the apparently subordinate disciplines have all evolved to an arguably independent status, whereby the identity of their practitioners is habitually described in terms such as *I'm a neurologist* rather than *I'm a doctor*. The same argument perhaps applies to the individual subdisciplines of linguistics and phonetics, such as phonology and sociolinguistics, each of which can be claimed to have matured into an independent discipline over the past half-century. The autonomous status of phonology is exemplified in Goldsmith (1995), and that of sociolinguistics in Coulmas (1997). Morphology, syntax, semantics, and pragmatics are assumed still to be seen as subcomponents within linguistics, as illustrated in Aronoff and Rees-Miller (2001), though at least the last three of these are currently building toward a more autonomous standing. However, the accuracy of the classification of a given discipline as having an independent professional status perhaps matters less than its identification as a contributor of analytic (or other) terms to the vocabulary of speech as an inherently multidisciplinary subject. Finally, there is the historical, biographic dimension of writers, scholars, researchers, and inventors who, for over some 2000 years and more, have influenced

the development of phonetics and linguistics, and of these other contributory disciplines (as described, for example, in Weir (1990)).

Phonetics is normally thought of as one of the linguistic sciences and has historically concentrated on describing the substance of spoken language – that is, the articulatory, auditory, and acoustic patterns of sound that manifest the phonological code of the language concerned (*see* **Phonetics: Overview**; **Phonology: Overview**). Speech science is the experimental study of speech, and speech science and phonetics overlap in the subject usually called 'experimental phonetics,' which formerly, until the mid–20th century, was referred to as 'instrumental phonetics' (Hardcastle and Laver, 1997). Some would claim a more ambitious scope for phonetics, suggesting that it includes not only the substance of spoken language, but also formal and abstract aspects of the phonological code as such. In this wider view, phonetics (in the broad sense) is the superordinate subject that includes phonetics (in a narrow interpretation) and phonology. In such a view, the relationship between phonetics and linguistics is one wherein phonology is the overlap between them (Laver, 2000a).

In the broadest view of all, it has occasionally been suggested that phonetics should be seen as the scientific study of all aspects of speech, standing at the intersection of all subjects with any professional contribution to make to such a study (e.g., Laver, 1994, 2001). But even in this extreme formulation, the field of speech has grown so wide that the most that phonetics can reasonably hope to achieve is to learn enough about the other contributory disciplines to understand their fundamental concepts and their methodologies, in order to be able to work on a profitable interdisciplinary basis with specialists in each discipline. Speech technology is a salient example of such a necessarily interdisciplinary collaboration. This will be discussed in more detail (see later, Speech Technology), but the design and implementation of a computer-based interface that allows a human user to communicate by speech with a machine could not be achieved solely on the basis of phonetic and linguistic knowledge about speech. Prerequisites for developing a successful interface for human–computer interaction through speech include skills in human factors; in system design and software programming, from computer science; in computational linguistics, from the union of linguistics, logic, cognitive psychology, artificial intelligence, and computer science (Mitkov, 2003); in acoustics, from physics (Stevens, 1998); and in signal processing and hardware design, from electronic engineering. Similarly, speech and language pathology would be very much less effective as a discipline if it did not add to its phonetic and linguistic knowledge about speech an extensive understanding of the biological basis for speech, from speech science and medicine (Barlow, 1999; Windsor *et al.*, 2002), and a familiarity with pedagogic techniques of rehabilitation. Just as specialists in speech technology and speech pathology need adequate exposure to phonetics and linguistics, phoneticians working with speech engineers or speech pathologists and therapists need some acquaintance with the disciplines that provide basic input to these subjects.

The requirement to be able to hold intelligible professional conversations with colleagues in such a broad spectrum of disciplines has direct consequences for the advanced training of phoneticians, and phoneticians in the 21st century are therefore often obliged to try to become familiar with wide-ranging aspects of the life sciences, the physical sciences, and the engineering sciences, if they are to hold their own in multidisciplinary research collaborations.

Why People Study Speech

In a cognitive perspective, perhaps the most significant reason for studying speech is that speech is the carrier of language, the vehicle for reflective thought. The mental life of the human species might be merely a welter of emotion and unconsidered reaction if it were not for the gift of language, with its facility for framing conceptual propositions, ranging from the simple and the concrete to the complex and the most highly abstract. Equally, language is the essential articulation of the cognitive machinery of society, as embodied in the traditional and contemporary institutions of literature, education, science, commerce, law, and government.

Another reason for studying speech is that speech is the most interactive of all social human skills. People's personal experience of social life would undoubtedly have a very different form if the human species had not developed the ability to communicate through speech, because people use speech to initiate, calibrate, negotiate, and consolidate their social relations with others. In this social sense, speech is worth studying because more is learned about the social meaning of what it is to be human. In this same vein, speech is worth studying in order to find out what is universally characteristic of human beings as a species (Hauser, 1966), versus the specifics of a given culture and its language. By extension, it is worth learning what is general to a community, versus what counts as idiosyncratic variation at a personal level. Looking at pronunciation, for instance, it may be asked why (a question that will be revisited later)

the spoken languages of the world seem to use only a quite limited selection of contrasting sound patterns, from the total range of sound types that the speech apparatus is capable of producing. As a further generalization, the languages of the world tend to share broadly similar sound types from this restricted set of possibilities. More is learned about the communicative principles of language by exploring the criteria behind the selections made by linguistic evolution in this area. At the level of the relationship between a speech community and the speakers that make up that community, more is learned about the relationship between individuals and society by knowing how the speech of the members simultaneously serves both to mark their membership within the (regional and social) speech community and to individuate them within the community.

Specialists in some disciplines would also say that speech is the most complex skill that human beings ever attain. From a biomechanical point of view, for example, the timing and gradation of the neuromuscular control of the 80 or so (mostly paired) muscles that serve the so-called speech apparatus are especially complex. By comparison with the subtle, rapid, and coordinated actions necessary to produce speech, most muscular skills of coordination seem less demanding. To produce speech at a normal speaking rate, the brain has to issue some 1400 motor commands per second to the muscles of the speech apparatus. In terms of the complexity of the neuromuscular programming and monitoring of the physical movements involved, the skill of speaking outranks even the skills involved in taking part in Olympic slalom skiing, in world championship table tennis, or in the Tchaikovsky piano competition. Yet all normal speakers display this apparently effortless skill, sometimes for hours per day, for every day of their adult lives. It takes normal children some years to acquire the skills of speech production and perception, by a combination of innate and imitative processes, but, once a child has learned them, the skills of speech are lifelong, and are lost only through pathology or trauma.

Speech is hence a classic instance of the more general problem of the voluntary neuromuscular control of serial order underlying skilled actions (Lashley, 1951). If it were known how the brain controls the sequence of articulatory actions for speech, a paradigm could be formulated for understanding many aspects of the control of highly complex neuromuscular activities, such as walking over rough terrain, hand/arm/eye coordination in reaching for objects at arm's length, visually tracking erratically moving targets, or maintaining balance and forward momentum while surfing on a breaking wave. This claim, that the neuromuscular control of speech could act as a paradigm for understanding many rhythmical nonspeech activities, such as walking, has, however, been subjected to an important caveat. Kent (2004) argued that the muscles used in speech systems are in fact unique in their genetic, developmental, functional, and phenotypical properties, and thus differ in important ways from other muscles. He reported on investigations by a number of researchers who showed that some craniofacial and laryngeal muscles, for instance, differ quite markedly, both from other muscles in humans and from muscles in other animals; these differences reside in the unique properties of mixed populations of muscle fiber types, some of which have very fast contraction capabilities and prolonged resistance to fatigue. These properties serve the special needs of speech well, and Kent explored the idea that some aspects of these muscular differences may reflect a unique human specialization for speech.

The Functions of Speech

In a biological perspective, speech is a secondary function, notwithstanding its sophisticated communicative complexity. Spoken language exploits a biological apparatus that evolved to serve more primary functions, such as breathing, biting, chewing, sucking, swallowing, and clearing the throat. In particular, it seems more than plausible that the articulatory movements of speech organs, such as the tongue, developed evolutionarily from the matrix of movements involved in the chewing and swallowing movements used in feeding (Hiiemae and Palmer, 2003). The later development of speech for the function of propositional communication probably had its origin in the vocal signaling that expresses basic biological states, such as hunger and pain; affective states, such as contentment and distress; and informative states, such as assertions of aggression, affiliation, and personal identity. At the early stage, the development of human vocal signaling was on a par with the vocal signaling characteristic of animals such as the higher primates (*see* **Cognitive Basis for Language Evolution in Non-human Primates**).

If listeners of a prelinguistic era tended consistently to modify their own behavior as a result of interpreting such vocal signaling, as a sign of some state being experienced by the speaker, and speakers became aware of such a linkage, then it is possible to believe that this could have been the beginning of the development of a semiotic code of spoken communication based on a growing vocabulary of such signs. The association between a state experienced by a speaker, such as hunger, and the uttering of a vocal signal that a listener has come to understand as typically

co-occurring with this need plausibly evolves into a situation whereby the vocal signal is taken to function as a request for the listener to supply food. Additional factors are obviously also necessary, such as suitable intelligence on the part of the listener, and perhaps the existence of a rudimentary social organization that prompts the listener to adopt an altruistic role. The next evolutionary step toward making vocal signaling into a conventional semiotic code would be to make the vocal sign independent of the true state of the speaker, thus enabling the speaker to manipulate the reactions of the listener – for example, by pretending to be hungry, distressed, or aggressive, etc. At this stage, the communicative functions embodied in vocal signaling could as easily have been achieved by manual signaling, in a primitive type of sign language. That the development of communication in the human species was shaped more primarily toward the use of the vocal channel, rather than the gestural channel, was probably motivated by the practical advantage enjoyed by vocal signaling of leaving hands and eyes free for other simultaneous use (*see* **Sign Language: Semiotic Approaches**). A step of much greater scale would then have been necessary for a symbolic code to have evolved such that it could be described as language in its modern sense, however. In a truly linguistic code, the link between sign and referent needs not only to be arbitrary, but also to show double structure. This duality of structure characteristic of the spoken code of language consists of two levels of structure in the signs used. The elementary signs of spoken language (consonants and vowels) are combined into longer sequences (such as a word), in which it is the sequence rather than the constituent elements that carries meaning, through an arbitrary and conventional reference to some physical or abstract entity. In their turn, words can be combined into an indefinite number of longer sequences (phrases and sentences), the structural sequence of which carries meaning over and above the meanings of the constituent words.

This elaborate machinery of spoken language can potentially be used for a multitude of communicative purposes, such as stating propositional concepts, negotiating social relationships of great subtlety, persuading, dissimulating, or making excuses and promises. But it is perhaps salutary to reflect that the majority of purposes served by speech in everyday interaction (such as communicating greetings, partings, or salutations; expressing social solidarity, affection, unhappiness, or irritation; and establishing individual identity by performing introductions) may not be so very distant in function from those early displays of more basic biological and affective needs.

The formal linguistic study of speech treats language as literally disembodied, with differences among individual speakers being disregarded. But in reality, every utterance of spoken language has to be performed, on some speaker's actual vocal apparatus, and perceived, by some listener's actual auditory system. Understanding the way in which speech is produced and perceived makes it possible to reach a clearer understanding of the nature of spoken communication in general, which is a richer interchange of information than that ever conveyed by spoken language alone. (Most of the comments offered in this article so far have focused on speech production, but it deserves emphasis that understanding the acoustic and physiological basis of the human auditory system is perhaps one of the most challenging tasks facing student phoneticians, given that the ear, with its related neurological support, is by far the most complex of all sensory organs (Warrington, 1999; Møller, 2000).)

Every utterance of spoken communication consists of at least three strands of speech production: the articulatory events that represent the patterns of spoken language, the speaker's tone of voice on the occasion of the utterance, and the general voice quality of the speaker. All three strands communicate information for the listener to process auditorily. Spoken language communicates the verbal message constructed by the speaker, tone of voice communicates the speaker's affective and emotional state, and voice quality indicates the identity of the speaker. The strands of speech supporting spoken language and tone of voice are subject to interpretation, which depends on the conventions of the speaker's speech community. Just as the phonetic basis of spoken language varies from one culture to another, so (though to a lesser extent) do the interpretive conventions associated with tone of voice. For example, imitating another's utterances in a falsetto voice in one culture may count as an accusation of whining complaint; in another culture this may serve as an accusation of boasting, and in yet another, uttering a phrase in a falsetto voice can act as an honorific device, acknowledging respect for the listener addressed.

Voice quality has two substrands to it. One is the organic foundation of the speaker's vocal apparatus, in that the dimensions and geometry of the vocal organs genetically inherited from the speaker's parents inevitably add a certain coloring to the sound of the voice. As listeners, people have come to rely on a certain correlation between the external, physical appearance of a person (based on the same genetic inheritance) and the sound of the voice that the person produces. A loud, deep, resonant voice (heard on the telephone, for instance) is usually taken to

indicate that the speaker is a large, adult male. The listener may occasionally be disconcertingly wrong in reaching this conclusion, however. This is because of the plastic nature of the second substrand of voice quality. Overlaid on the organic foundation of a person's voice is the habitual, long-term pattern of phonetic use of the vocal apparatus that the speaker has learned to adopt. A given speaker's voice may be characterized by a habitual tendency to constrain the pitch of the voice to a low register, or to speak consistently loudly, or to produce strong nasality, or to keep the lips in a rounded position throughout speech, or to pronounce all voiced consonants and vowels with whispery phonation, etc. (Laver, 1980; Gobl and Ní Chasaide, 2003). This second element of voice quality often characterizes a whole speech community and can therefore mark regional or social groupings (*see* **Voice Quality**).

The accent of a speech community can be reflected in all three strands – the pronunciation of spoken language, the patterns of tone of voice, and the phonetic component of voice quality. The American English accent of the Bronx in New York and the British English accents of speakers from Birmingham and Liverpool are marked by a habitual long-term voice-quality adjustment that tends to keep the back of the tongue elevated during speech (technically called 'velarization'). Such a tendency to constrain the articulatory activities of the body of the tongue has its impact on the way that individual vowels are pronounced, in this case compressing the utilization of the vowel space in an upward and backward direction. Since vowel quality also functions to represent the phonemes of spoken language, and partly to carry information about the affective or emotional state of the speaker through tone of voice, it follows that the communicative value of any given phonetic vowel quality is quite complex. It also follows that the instinctive sense that patterns of tone of voice have the same communicative value in all cultures, as a universal feature of human communication, may be quite misplaced, as mentioned previously. The aspects of tone of voice that do more plausibly carry a degree of universal interpretability are those that are dependent on endocrinal biochemical states, such as extreme fear.

The Scope of a Descriptive Theory of Speech

In the light of the three strands of speech, each with their corresponding information about different aspects of the speaker, what should be the ideal scope of a descriptive theory of speech? From the point of view of a **linguistic** motivation for a comprehensive description of the substance of spoken language, such a theory should obviously be able to describe the phonetic basis for the differentiation of words and other linguistic units in every known human language. From the perspective of a **sociophonetic** motivation, the theory should be able to describe the phonetic regularities that serve to distinguish one accent from another accent, and that make each language sound different from other languages. Equally, the theory should be able to describe the way that speakers change the formality of style of their speech according to the types of listeners whom they are addressing, and the context of situation in which they are speaking. From a **paralinguistic** viewpoint, the descriptive competence of the theory should extend to being able to characterize the phonetic events that are conventionally used as signals of attitude and emotion in each culture, together with the phonetic cues conventionally used to claim and yield the floor in the control of speaking-turns in conversational interaction in each culture. Finally, for **extralinguistic** purposes, the theory should be able to account for the phonetic phenomena that are taken to mark each individual speaker's personal attributes of physical identity, personality, and regional origin.

Given these prescriptions for the descriptive scope of an ideal theory of speech, it is perhaps relevant to pose the question of how the capabilities of existing theory match such requirements. It is probably fair to suggest that the linguistic capabilities of modern phonetic theory are fairly comprehensive, within the limits of the known languages of the world. The sociophonetic requirements are much less well served, with the attention of researchers beginning to turn only around the early 1990s to the need to be able to account for sublinguistic differences between accents, and style being still a relatively new area of investigation. Paralinguistic investigations of tone of voice are not at the time of writing competently described on any comprehensive basis for any culture, and the description of extralinguistic properties of speakers, such as the quality of their voices, remains a minority interest (Laver, 2000b).

One sector in the study of speech in which extralinguistic research is beginning to accelerate, however, is in speech technology, wherein the characteristics of individual speakers constitute both a challenge (in speech synthesis) and a problem (in speech recognition). Another sector in which interest in the extralinguistic properties of speakers' voices has always been central is speech pathology. The role of both of these sectors in future developments in the study of speech is discussed further in the following sections.

Variation and Change in Speech

Spoken language is a social organism, and its evolution, like that of other more directly biological organisms, changes through both (apparently random) drift and adaptation to circumstance. Speech patterns act as a strong index of membership of social groups, and one major adaptive influence toward evolutionary change is a shift in the patterns of relative dominance (through invasion, fashion, or economic influence, say) between social groups. As one social group becomes dominant over another, the accent of the dominated group tends to change toward that of the dominating group. On a timescale longer than that of the life of an individual speaker, the accents of speech communities are hence in a continual state of flux. As participant observers, linguists can glimpse these patterns changing in their individual detail, but the global shifts in pattern are available only to the analyst in the mirror of history. There might be success in understanding authentic pronunciations of Shakespeare's English, but it would be harder to understand Chaucer's English without interpretive help. With the passage of time, and the right social conditions of lack of interaction, the accents of initially comparable speech communities can drift progressively apart, eventually to the point of mutual unintelligibility of separate languages. The English spoken in Britain and America, similar around 1600, has not yet reached such extremes of divergence, largely because of the maintenance of contact through trade and technology.

At the level of individual speakers, some reasons have already been given why speakers sound different from each other, and why the tone of voice of a speaker on different occasions might sound different because of his or her affective or emotional condition. But the voice of an individual speaker also changes throughout life, in growth from childhood to maturity, and from maturity to old age (Mackenzie Beck, 1997). One of the most striking phenomena in the general experience of speech is the way that the voices of males and females change with age, basically due to their sex-specific patterns of anatomical development. In childhood, there is not a great deal of difference between the voices of boys and girls that can be explained by sex-specific aspects of differing dimensions of the vocal apparatus, until the children approach puberty. Such prepubertal differences as there are between the voices of girls and boys are likely to have a phonetic rather than an organic basis, as children begin to learn to reproduce patterns of speech signaling the adoption of social roles specific to gender. Once puberty sets in, however, the voices of boys and girls tend to diverge swiftly, for organic reasons. In the case of boys at puberty, the dimensions of the larynx change very rapidly (typically within a few months), with the length of the vocal folds nearly doubling and the average pitch of the voice halving. In the case of girls, the change in laryngeal dimensions is much smaller. The increase in length of the vocal folds in pubertal boys is of the order of 1 cm, whereas the increase in pubertal girls is only about 3 to 4 mm. The result is that young men's voices drop markedly in average pitch by comparison with their prepubertal state, but voices of young women drop only slightly. As a very broad generalization, the average pitch of young male adolescents is about an octave lower, compared to the average pitch of young female adolescents.

The voices of children (of both sexes) and adult women thus have more in common than do the voices of young boys and adult men, at least in terms of the influence of laryngeal dimensions. This is true not only when comparing laryngeal development, but also when considering the relationship between the dimensions of speakers' vocal tracts. The lengths of adult male vocal tracts are characteristically longer, on average, than are those of adult female vocal tracts. These differences of overall vocal-tract lengths between typical male and female vocal tracts can be treated as the product of a simple scaling factor. However, the relative proportions of different sections of adult female and adult male vocal tracts cannot be treated in the same way, in the sense that the ratio of pharynx length to mouth-cavity length is greater for males than for females (Fant, 1966). One consequence of this is that the vocal tracts of women cannot simply be regarded as typically being smaller than those of men by a simple scaling proportion, and this is one organic basis for the different perceptual quality of women's and men's voices. The dimensions and relative geometry of the vocal tracts of children are proportionally related to those of women in terms of the ratio of the length of the pharynx to that of the mouth section. The growth profile of young men beyond puberty then changes the ratio and increases the nature of the difference between their voices and those of women of the same age cohort.

The voice also changes in older age (Linville, 2001). One of the principal changes, beginning in the 20s, is progressive calcification of the vocal cartilages, including those of the larynx, making them less flexible. In later age (from about 50 or so in women and about 60 in men), the muscular tissue of the vocal folds tends to atrophy to a certain extent, and to lose some of its elasticity, so that the vibratory pattern of the folds in phonation becomes less efficient. The muscles and cartilages of the chest are similarly affected, and the respiratory support for speech

becomes less able to be finely coordinated. The progressive result is that the quality of the voice of extreme old age is typically characterized by inefficient phonation (often sounding whispery, and sometimes hoarse), with a restricted range of pitch, and weak loudness. Male and female voices differ with regard to pitch level in old age. The average pitch level of men's voices tends to rise slightly from ages 65 through 85, but the average pitch of older women's voices tends to be more or less unaffected.

A person's voice also changes on a shorter timescale than across the whole of a lifetime. An obvious example of a more ephemeral change, though still of potentially long duration, is when the speaker develops a laryngeal disorder that affects the quality of the voice. These disorders may have a functional cause. Teachers, factory workers, or anyone obliged to speak very loudly for long periods against a noisy background can develop nodules on the vocal folds through habitual use of overvigorous phonatory habits, giving the voice a rough quality. Vocal abuse of this sort can usually be remedied with the help of speech therapy. A rough voice that persists for more than a short period may alternatively have its origin in a pathological condition, requiring diagnosis by a laryngologist, who may prescribe treatment ranging from phonosurgery, radiotherapy, and chemotherapy to speech therapy, or some combination of these (Colton and Casper, 1996). Once again, there seems to be a difference in the susceptibility of men and women to the more potentially life-threatening of these disorders, with more male patients than female patients being diagnosed as suffering from laryngeal cancer. Happily, cancer of the larynx is one of the most treatable forms of cancer, given sufficiently early diagnosis.

Structural anomalies of the vocal tract, such as being born with a cleft palate, also directly affect the quality of the voice and speech. Structural anomalies tend to be repaired surgically in early and middle childhood, with speech therapy being available for help with learning the speech patterns appropriate to the changed structure, if necessary. A more drastic problem occurs in disorders of the vocal tract such as intraoral tumors, which usually require either surgery or radiotherapy or both. The challenge for the speech therapist after surgery, if the anatomical structure of the vocal tract has been significantly changed, is then to help patients to restore the intelligibility of their speech to an acceptable and useful level. The vocal apparatus is extremely versatile, however, and with the help of the therapist and compensatory articulatory strategies, many patients successfully learn new patterns of articulation that produce auditorily intelligible speech.

The more ephemeral changes in a person's voice happen when short-term illness strikes, such as respiratory infection, tonsillitis, or temporary laryngitis. On a yet shorter term basis, conditions such as fatigue, excitement, and inebriation also affect the voice.

It is a truism that no single speaker ever pronounces a given syllable in precisely the same way twice, at a microscopic acoustic level of analysis. There are both systematic and random reasons for this variation. Systematically, the pronunciation of a given syllable will vary with the linguistic context in which it occurs. This linguistic context is defined by factors such as word stress, the numbers of other syllables in the same word, the numbers of other words in the same rhythmic or intonational phrase, the place of the syllable in the rhythmic or intonational phrase, the particular type of intonational pitch contour being applied to the phrase, the placement of the pitch contour within the speaker's general pitch range, the choice of overall loudness used, the place of the syllable in the overall utterance, the style of speech, and the overall rate of speaking the utterance (not to mention the factors exploited for differences of tone of voice). When all of these factors are permuted, and all of the noticeable gradations of each factor are included, the total number of perceptually distinguishable variations becomes extremely large.

The pronunciation of a given syllable by an individual speaker also varies acoustically on a quasi-random basis, even when all other factors are stabilized by trying to repeat exactly the same phrase twice in exactly the same way. This is perhaps understandable, recalling that the detailed strategies of neuromuscular control are largely outside conscious access. For an exact copy of a particular utterance to be produced successfully, every single muscular contraction of the muscles of the vocal organs, from the respiratory system to the articulatory system, would have to reproduce the same pattern, with precisely the same timing, on the second occasion.

Motor Equivalence and Perceptual Equivalence in Speech

A more revealing version of the speaker's task of reproducing a copy of a given utterance is one wherein the speaker must reach a target configuration of the vocal tract from a variety of starting configurations. This is comparable to the task of a fielder in baseball throwing a ball from any part of the field of play to reach first base, where the means will be conditioned by the spatial relationship between the fielder's current location and that of first base, but

where the end (the ball arriving at first base) is constant. In order to succeed in conquering this problem, the brain of the fielder/speaker must compute and execute a neuromuscular plan of action that takes account both of the (highly contingent) starting configuration of the relevant muscular apparatus and of the transformations of this necessary to reach the state that will achieve the desired result. For the brain to succeed in such a task, it is clearly out of the question to propose that a neural blueprint for every possible separate neuromuscular command is stored in long-term memory. The storage capacity of the brain is simply not sufficient, with only some 10 000 million nerve cells. The neuromuscular principle underlying such a task of achieving specific ends through contingent means was discussed by MacNeilage (1970), in his account of the work of psychologists such as Hebb (1949: 153–157):

> Although it has been neglected by linguistically oriented models of speech production, the problem of accounting for 'a variability of specific muscular responses, with circumstance, in such a way as to produce a single result' has been recognized by some psychologists as a 'ubiquitous fundamental psychological problem' and the phenomenon has been termed 'motor equivalence.' [MacNeilage, 1970: 186]

The principle underlying motor equivalence is inconsistent with a simplistic model of speech production that merely selects the appropriate neuromuscular command pattern from a colossal store of neural blueprints. An alternative is that people store some more limited set of target representations, and have general strategies for moving from a starting configuration through some designed trajectory to the desired final state (Laver, 1991: 23–84). What is most surprising, perhaps, is that listeners – despite the extraordinary number of possible acoustic variations that they hear from different speakers of different sexes, of different ages, of different accents, on different occasions – can nevertheless succeed in decoding the intended messages, and usually without apparent difficulty. A phenomenon that might be called 'perceptual equivalence' could be thought to underlie such a versatile performance. That successful speech communication necessarily demonstrates the simultaneous solution of the joint problems of motor equivalence and perceptual equivalence is a commentary on the robustness of the strategic design reflected in the skills involved in speech.

The Sound Patterns of Spoken Language

A remarkable aspect of speech as a manifestation of spoken language, as noted earlier, is that the distinctive, phonemic differences between accents of a given language (Kretzschmar, 2004; Wells, 1982), between different languages of the same language family, and indeed between unrelated languages from different language groups (Ladefoged, 2005) are so (relatively) minor. Compared with the enormous range of sounds that the human vocal apparatus is capable of making, the known languages of the world seem to exploit a quite limited fraction of different sounds and to organize them into contrasting phonemic systems of (very broadly) comparable size.

In an investigation of the sound systems in the University of California Los Angeles Phonological Segment Inventory Database (UPSID) database of 317 languages selected as representative of the language families of the world, Maddieson (1984: 7–9) explored the size of phonemic inventories involved. At the smallest end of the range were Rotokas (an Indo-Pacific language) and Hawaiian (an Austro-Tai language), with phonemic inventories of only 11 segments (6 consonants and 5 vowels) for Rotokas and 13 segments (8 consonants and 5 vowels) for Hawaiian. At the largest end of the range was !Xũ (Kung-Ekoka), a Khoisan language of southern Africa, with 141 segments (95 consonants and 49 vowels). The statistically typical size of a combined consonant and vowel inventory for a language in the UPSID database was between 20 and 37 segments, with 70% of the 317 languages falling in this range. The average number of segments used contrastively by the languages of the database was 31. Given that the languages of the UPSIDdatabase are in fact representative of the spread of languages in the world, as intended, then such a small range of size of phonemic inventory for more than two-thirds of the languages concerned is noteworthy.

Within the small range of inventory size, the sounds exploited are not so very different from one language to another, in general. Almost all languages exploit [t], [n], and [s] among their consonants, and very many use the vowels [i], [a], and [u], for instance. A very small number of spoken languages use click sounds as consonants, and none makes contrastive use of percussive sounds created by clashing the teeth together, or scrapive sounds produced by grinding the teeth, or snoring sounds. None is known to use falsetto phonation in contrast to normal voice for linguistic purposes. Many cultures use some of these sound types for paralinguistic purposes of communicating emotion or affect, but their use as linguistic elements of spoken language as such is unknown.

How has this relative standardization come about, and on what principles might the human species have chosen such a limited range of contrastive patterns from the full vocal range? The adjective

'anthropophonic' has been used to refer to the concept of the 'full vocal range' of the sound-making capabilities of the human vocal apparatus, and this label will be adopted here for convenience of discussion. The first point to make is that the anthropophonic potential of the vocal apparatus is distributed unevenly through articulatory space, as it were, in that the relationship between articulatory adjustment and auditory consequence is not standard in all articulatory zones. In some zones, a small articulatory adjustment produces a large auditory difference (such as at the alveolar ridge and the front teeth, in the production of sounds like [s] in *sin* and the voiceless dental fricative sound in initial position in *thin*); in other zones, a small articulatory adjustment makes not much difference (such as at the soft palate, in the articulation of sounds such as [k] in *kin*). It is clearly of benefit to the functioning of a robust communicative system that the evolution of spoken language should have preferred the latter to the former, so that speakers were relieved of the need to maintain maximum articulatory precision. Equally, the selection of these more stable relationships between articulation and perception might be thought to ease the listener's task of decoding speech, by reducing the apparent variety of articulatory performance. Finally, the natural beginnings of a categorial structure to the perceived inventory of speech tokens could plausibly emerge from such islands of articulatory/auditory stability. Stevens (1972) referred to these relationships as indicating 'the quantal nature of speech.' (Ohala (1989) also edited a theme issue of the *Journal of Phonetics* on this topic, which is recommended to the interested reader.)

The remaining four points to make are based partly on three publications by Lindblom (1983, 1986) and Lindblom and Maddieson (1988). The first is that the choice from the anthropophonic potential has to ensure adequate perceptual contrast if the sounds chosen are to sustain a distinctive function in the code of spoken language. Evolutionary pressure in the development of effective communication would have acted against the selection of sound types that were difficult to distinguish consistently, such as a voiceless fricative sound made with the tongue tip against the inner surfaces of the upper front teeth, versus a similar but slightly different sound made with the tongue tip between the teeth. The next point is that the sounds chosen have to display ecological robustness, in that they have to maintain their distinctiveness when pronounced against a background of environmental noise, including competing speech from other speakers. Next, the production of such sounds has to show ease and economy of articulatory performance, without pushing the articulatory system to the limits of anthropophonic complexity. Finally, the sounds chosen ideally have to be readily modifiable to the needs of the communicative situation, and to be capable of being said more rapidly or slowly, more softly or loudly, and with higher or lower pitch, without undue effort.

Any system of speech sounds that displayed all five of the characteristics discussed here would presumably be optimally easy to learn, easy to use, and robust in the face of masking by noise. However, it is difficult for any individual language to satisfy the full set of criteria simultaneously, and most languages therefore show a degree of compromise in their evolutionary obedience to these different principles. Combining the fact of continual sound change in language with the observation that the contrastive utilization of speech sounds by languages tends to choose from the same fraction of the anthropophonically available sounds, it is evident that as the sound system of a language changes, the sounds chosen are likely to show trading relationships among the five criteria listed.

The ubiquitous tool used by phoneticians for the description of the variety of sounds in the 6500 to 7000 different languages of the world is the International Phonetic Alphabet. This is revised from time to time by the world body of phoneticians, the International Phonetic Association (IPA, 1999). But it has to be said that the majority of changes nowadays rather reflect developments of descriptive phonetic theory, together with an acknowledgment of the needs of professions such as speech/language therapists and pathologists, more than the relatively infrequent discovery of sound types being put to novel distinctive or contextual use in some newly researched language. This latter possibility of new discoveries becomes slowly even more remote as the last few speakers of a regrettably increasing number of endangered languages die, and some existing languages of minority populations languish under political pressure from speakers of more populous languages (Grenoble and Whaley, 1999).

The Integration of Speech with Other Channels of Communication

The context of everyday speech is normally that of conversational communication in a face-to-face situation. In face-to-face conversation, speech is only one of the different channels of information carrying communicative significance. Gesture, head movements, posture, interpersonal proximity, eye contact and gaze direction, and facial expression all play their part in conversational communication under conventions of interpretation that are just as culturally

specific as are those of tone of voice. What counts as comfortable proximity in a formal conversation may differ radically from culture to culture, with a given distance between two unacquainted interlocutors being simultaneously sensed as uncomfortably remote and formal by a speaker from a Middle Eastern culture, and distressingly overfamiliar by a speaker from North America. The proximity and posture taken up by interlocutors in a conversation can signal their view of their relationship as clearly as do the tone of voice used and the linguistic messages exchanged. The nonvocal message communicated by proximity and posture reinforces (or sometimes contradicts) the vocal messages of spoken language and tone of voice. In either event, the nonvocal and the vocal channels of communication together comprise an integrated communication system (Laver, 2002).

The timings of gestures, head movements, eye contacts, gaze direction, and facial expression tend to be synchronized, so that the nonvocal actions of an interlocutor in a conversation are managed as an integrated performance. It would then be somewhat surprising if the vocal actions of speech were performed out of synchrony with this multichannel nonvocal performance, and thus vocal and nonvocal actions tend to be prescribed by the same orchestral score, as it were. Emphatic hand gestures tend to coincide in time with the use of devices of vocal emphasis, such as the intonational changes of pitch associated with sentence stress, as do head movements. Signals of eye contact and facial expression are often used as floor-management devices to effect (or resist) the exchange of speaker role in conversational turn-taking. To withhold eye contact at the end of an utterance, while simultaneously constraining an intonational fall in pitch to end less than maximally low in the pitch range, is conventionally to deny the listener the opportunity to take over the speaking turn, in conversations in English-speaking cultures, for instance.

Speech Technology

Although conversational communication in a face-to-face situation is the norm for the vast majority of spoken interactions, the spread of telecommunications means that telephone conversations with remote interlocutors is a thoroughly normal, everyday experience for many more than a billion people. The telephone has the potential to become the prime means of exposing many people to a communication-technology revolution that may, in the longer term, be comparable in social impact to the invention of mechanized printing – namely, the development of human–computer interaction through speech technology. In particular, the telephone is playing an important familiarizing role in exposing people to speech technology in the form of automated operator services that incorporate both automatic speech recognition and speech synthesis in rudimentary forms of conversational dialogue. Partial automation already exists, for example, in British Telecom's Directory Enquiry services: the operator connects the caller to a speech synthesis system to read back the number asked for. In the United States, several fully automated services exist, including an automated 'collect call' facility ('reverse charges,' in British vocabulary). It seems likely that, following this familiarization, users will more readily adopt speech technology facilities in office automation and in the workstations in clinical and educational applications under development in laboratories.

Automatic speech recognition systems have been demonstrated to be capable of recognizing sentences of continuous speech from a variety of speakers, in tasks with constrained vocabularies of some thousands of words, in applications as diverse as travel inquiries and medical report generation. Systems that recognize words pronounced in isolation have vocabularies in excess of 100 000 words, and can be used for text generation on more or less random topics. They allow a user to generate and edit text faster than an average hunt-and-peck two-finger typist can type, but are not as fast as professional typists. With speech recognition systems of this scale of competence, many applications are becoming feasibly cost-effective; although the pattern of industrial growth in this technical area is still slower than enthusiasts had predicted, North America, Japan, and Europe are already seeing fairly numerous commercial developments (*see* **Speech Recognition, Automatic: History**).

To illustrate the place of speech technology in overall developments in the study of speech in general, consider the case of speech synthesis: do specialists in the disciplines concerned with speech technology know enough about speech to construct a synthetic voice that could be mistaken for a genuinely human voice? To the extent that this cannot yet be achieved except by using small segments of recorded human speech concatenated together, not enough is known about the scientific basis for speech production. Using concatenated excerpts from real speech gives a quality that is close to natural, but usually still fails to adapt to specific local demands for microadjustments of intonation and related aspects of tone of voice that would be necessary for complete naturalness.

The ideal generic capability of speech technology should be the development of an effective text-to-speech (TTS) conversion system for any of the world's natural languages with a writing system,

with a performance comparable to that of an experienced human reader of that language. In the case of English, this could be interpreted as the capacity to design and build a TTS system able to generate a natural, intelligible, acceptable, and usable pronunciation of any well-formed sentence capable of being written in English by any nontechnical writer. No TTS system currently available, however, completely fulfills this description for every sentence it could be called on to pronounce. Guarantees of natural quality, of full linguistic intelligibility, and of widespread user acceptability are all (even if only slightly) beyond the reach of every system built to date. An ultimate test of a TTS system would be to require it to read a novel aloud, such that the sentences attributed to individual speakers in the story were convincingly pronounced in a tone of voice appropriate to all possible style markers in a narrative text, as in *"Run for the fire brigade!," she cried in a distraught and fearful voice*. Paralinguistic analysis is perhaps many decades away from being able to specify a full catalogue of such tones of voice, so that they could be exploited by rule in a TTS system.

In setting targets for the performance of synthesis systems, it is helpful to distinguish between two intersecting axes: quality and habitability. In terms of the quality axis, the output of a synthesis system can be perceptually compared with human speech, and rated comparatively on dimensions of naturalness, intelligibility, and comprehensibility. Naturalness is a scale running from fully natural through naturalistic to fully synthetic. Naturalness, moreover, is not the same as intelligibility. A synthetic voice can be fairly intelligible, but thoroughly unnatural (as in the case of most existing synthesis systems). It can also be relatively natural but nevertheless unintelligible (as in the case of a muffled human voice heard and identified as human – but not understood – through a closed door). When a synthetic voice is relatively but not fully natural, it can be called 'naturalistic.' A version of the Turing test could be proposed to distinguish between 'natural,' 'naturalistic,' and 'synthetic' classifications of a given voice. For a voice to be classed as 'natural,' human listeners would have to be certain that the voice originated from a human speaker. For it to be classed as 'naturalistic,' it would be necessary for them to be uncertain about whether the voice originated from a human speaker. For it to be classed as 'synthetic,' listeners would have to be certain that the voice did not originate from a human speaker. The best synthesis systems available at the time of writing could reasonably be described as 'natural in patches' (*see* **Speech Synthesis**). Such systems can reach intelligibility levels that, at best, are intermittently equivalent to those that characterize a human reader. However, intelligibility is not a feature that resides only in the speaker, whether human or machine. It is also conditioned by attributes of the listener, and what counts as guaranteed intelligibility for a native listener will not necessarily achieve the same performance in the perception of a foreign listener. Whether synthesis of a natural quality is ultimately a desirable facility in speech output systems is debatable. It could be argued, for example, that it will always be preferable for human listeners to know that they are listening to a machine rather than to another human. There are many possible ways of ensuring the latter, however, and setting natural quality as a research objective for synthesis is seen as a useful strategy for making speech synthesis available to the widest range of different speech technology applications.

The testing of the intelligibility of synthetic speech, at the level of the lexical identifiability of individual words, is well developed.The testing of the comprehension of synthetic speech, in terms of successful communication of the semantic and pragmatic import of the complete message transmitted, at the level of the phrase, sentence, or whole text, has scarcely yet begun. Well-established techniques exist for such testing of comprehension, in fields such as foreign-language testing, which are likely to be a valuable future source of methodology for speech synthesis interests.

In terms of the habitability axis, it is possible to distinguish between issues of acceptability and those of usability. The quality factors of naturalness, intelligibility, and comprehensibility inevitably color both of these habitability topics. Acceptability issues concern the speech-mediated relationship between the user on the one hand, and the TTS system treated as a quasi-human interlocutor on the other. Salient among acceptability issues are therefore matters to do with the perceived identity and attributes of the quasi-human synthetic speaker, based on voice type. Cosmetic factors of pleasantness, perceptual factors of robustness in the face of ambient noise (including other speech), and general factors of cognitive comfort all play their part here. Usability issues impact both the willingness of a human user to interact with a TTS system as an information device, and the efficiency of the combined system made up of user and TTS system addressing a given task. Usability is thus a product of the interaction between the system, the user, and the task. It involves ergonomic considerations and productivity aspects of effectiveness of task completion. Relevant issues here include those of dialogue structure and management, the clarity of the user's understanding about the system's knowledge of the relevant semantic and linguistic aspects of the task

universe, and the system's ability to adapt to changing informational conditions. The methodology to establish and calibrate such factors of habitability is still underdeveloped in many respects, and constitutes an urgent task for the discipline of speech technology.

The Future of Speech Research

The key development in speech research since about 1960 has certainly been the advent of the computer. Its arrival has brought a new dimension to the study of speech, not just in enabling developments in speech technology. A major consequence has been that the nature of what counts as possible data has changed. The scale of plausible speech data once consisted largely of what an individual analyst could gather through personal, face-to-face interaction with informants. Experimental conclusions were usually justified on the basis of sets of informants that seldom exceeded 30 individual speakers. The range of variation in such data was therefore usually restricted, and it was hard to be confident that the data represented the properties of speech in general, rather than solely those of the speech of the specific informants in the experiment.

The arrival of computers of economic cost and substantial processing power, supported by large-scale funding for collaborative interdisciplinary projects in speech technology, has had the result that the collection of speech data and its organization into manipulable databases have required operations on a quite different scale. It is not uncommon to read a research report of a study on the production of a particular type of consonant, say, in which several thousands of tokens were collected, automatically processed, and analyzed acoustically, by computer. The robustness of conclusions drawn on this basis is of a quite different order from that of earlier, inevitably sparser work.

Research on speech was represented at the beginning of this article as a necessarily interdisciplinary enterprise. The most significant disciplinary development in speech research over the second half of the 20th century was undoubtedly the growth in the alliances of phonetics with speech science, on the one hand, and with the engineering and information sciences, on the other. The first of these alliances provides the foundation for what promises to be a significantly improved understanding of the biological and physical bases of speech. The second alliance promises a transformation in the relationship between humans and machines. The 21st century should therefore show a flowering of some of the broad interdisciplinary potential of speech research.

Speech Accommodation Theory and Audience Design

A Bell, Auckland University of Technology, Auckland, New Zealand

Accommodation theory is an approach to language style developed by the social psychologist Howard Giles and associates since the 1970s. Accommodation is "the adjustment of one's speech or other communicative behaviours *vis-à-vis* the people with whom one is interacting" (Giles, 2001). Initially called Speech Accommodation Theory (SAT), it was broadened in the 1980s to encompass wider aspects of interaction under the label of Communication Accommodation Theory (CAT).

In its early stages accommodation theory was concerned with the causes and consequences of the convergence or divergence of speech styles. The model proposed that speakers accommodate their speech to their addressee in order to win their approval (Giles and Powesland, 1975). This means that the common form of accommodation is convergence, by which speakers shift their style of speech to become more like that of their addressees. A range of experiments (e.g., Giles and Smith, 1979) demonstrated how speakers converge with other each other on a number of levels such as speech rate, accent, content, and pausing. Studies have shown that convergence tends to be positively evaluated by recipients, being registered as a desire for social integration, identification, and approval. Giles, Taylor, and Bourhis (1973) found that in the bilingual context of Montreal, the amount of effort a speaker was perceived to have made in language choice between French and English affected how highly they were evaluated.

Classically, convergence occurs when a speaker intends to converge; linguistic analysis shows that this has indeed occurred; and the psychological climate of the interaction is one of interpersonal association (Giles, 2001). Convergences have been categorized under various distinctions, usually binary. A convergence may be upward or downward, depending on the relative social status of the interlocutors; full or partial, depending on how far a speaker moves

Speech Accommodation Theory and Audience Design

A Bell, Auckland University of Technology, Auckland, New Zealand

Accommodation theory is an approach to language style developed by the social psychologist Howard Giles and associates since the 1970s. Accommodation is "the adjustment of one's speech or other communicative behaviours *vis-à-vis* the people with whom one is interacting" (Giles, 2001). Initially called Speech Accommodation Theory (SAT), it was broadened in the 1980s to encompass wider aspects of interaction under the label of Communication Accommodation Theory (CAT).

In its early stages accommodation theory was concerned with the causes and consequences of the convergence or divergence of speech styles. The model proposed that speakers accommodate their speech to their addressee in order to win their approval (Giles and Powesland, 1975). This means that the common form of accommodation is convergence, by which speakers shift their style of speech to become more like that of their addressees. A range of experiments (e.g., Giles and Smith, 1979) demonstrated how speakers converge with other each other on a number of levels such as speech rate, accent, content, and pausing. Studies have shown that convergence tends to be positively evaluated by recipients, being registered as a desire for social integration, identification, and approval. Giles, Taylor, and Bourhis (1973) found that in the bilingual context of Montreal, the amount of effort a speaker was perceived to have made in language choice between French and English affected how highly they were evaluated.

Classically, convergence occurs when a speaker intends to converge; linguistic analysis shows that this has indeed occurred; and the psychological climate of the interaction is one of interpersonal association (Giles, 2001). Convergences have been categorized under various distinctions, usually binary. A convergence may be upward or downward, depending on the relative social status of the interlocutors; full or partial, depending on how far a speaker moves

toward her interlocutor; symmetrical or asymmetrical, depending whether the shift is unilateral or not.

Alternatively, instead of converging, speakers may maintain their style of speech or even diverge from their addressee. Divergence is regarded as a tactic of intergroup distinctiveness, by which individuals or groups differentiate themselves from other individuals or groups. As later studies have shown, however, there is no automatic interpretation of the meaning of convergence, as it can in some circumstances be construed as psychological divergence.

The social psychological aspect of accommodation theory became increasingly complex as it tried to encompass facts such as these that do not sit easily with simple convergence or divergence. The theory originally suggested that the greater the desire for approval, the greater would be the convergence. Some early experiments (e.g., Street, 1982) do show that. However, Giles and Smith (1979) found that speakers can converge too much, causing addressees to react unfavorably to what they may feel is patronizing or ingratiating behavior. Conversely, addressees need not always disapprove of divergence.

Riders to the theory have proliferated, especially in the comprehensive refinements by Thakerar *et al.* (1982), Coupland *et al.* (1988), and Giles *et al.* (1991). Thakerar *et al.*'s (1982) three-dimensional model of accommodation allows for a complex range of options and remains a core statement of the sociopsychological foundation of the theory. They introduced a distinction between psychological and linguistic accommodation, including the possibility that a speaker may converge linguistically while diverging psychologically.

Coupland *et al.* (1988) expanded accommodation to a wider set of attuning strategies, specifically in health- and age-related communication, by which communicative dimensions other than language are accommodated to a speaker's perceptions of an interlocutor. Giles *et al.* (1991) explored the distinctions that have been made in accommodation theory, providing a detailed historical view of the development of the theory to that time. Further aspects of convergence and divergence are characterized, including uni- versus multimodal and subjective versus objective accommodation. They acknowledge the possibility that, given the multiplicity of linguistic and extralinguistic features involved in any interaction, a speaker may converge in some features and diverge in others.

The weight of accommodation theory's apparatus thus expanded in the 1980s to cover the more nuanced findings that were emerging through empirical work. Elaboration of the theory has not extended greatly since then, doubtless in part because the models had already become very complex and not easily capable of further refinement. However, the basic insights of accommodation remain sound: that speakers accommodate their style to their audience. If we understand accommodation encompassing any style shift that occurs in response to an audience, the theory is a powerful explanatory model of style. It goes beyond the descriptive taxonomy and nondirectional correlation in earlier sociolinguistic approaches to propose an explanation of what causes style shift. Shepard *et al.* (2001) provide a review of accommodation studies to the end of the 20th century. Contemporary research continues to use the accommodation framework as an approach to a variety of sociolinguistic issues such as gender-related accommodation by children (Robertson and Murachver, 2003) and accommodation in intergenerational communication (Williams and Garrett, 2002).

To linguists, early accommodation theory's chief deficiency was its linguistic naïveté, dealing largely in quasilinguistic parameters such as speech rate or utterance length, or intentionally unsophisticated ratings of whole accents. By the 1980s some sociolinguists came to accommodation theory to explain the patterns they were finding in their study of specific linguistic features. Conversely, both social psychologists (e.g., Giles, 1973) and sociolinguists (e.g., Bell, 1984; Coupland, 1984) had critiqued the accepted Labovian paradigm (1966) that held that style was controlled by the amount of attention paid to speech. Major studies by Bell (1982) and Coupland (1984) were early examples of a more fine-grained sociolinguistic analysis that utilized the insights of accommodation theory (see also Trudgill, 1981).

The most widespread approach to style in sociolinguistics (Eckert and Rickford, 2001) has been audience design, which has close parallels to accommodation theory, but arose disciplinarily from (socio)linguistics rather than social psychology. Developed by Bell (1984), who derived the term from Clark (Clark and Carlson, 1982), audience design proposes that speakers' style choices are primarily a response to their audience. The framework has been summarized (Bell, 1997, 2001) under nine headings:

1. Style is what an individual speaker does with a language in relation to other people. Style is essentially interactive and social, marking interpersonal and intergroup relations.
2. Style derives its meaning from the association of linguistic features with particular social groups. The social evaluation of a group is transferred to the linguistic features associated with that group.

Styles carry social meanings through their derivation from the language of particular groups.

3. The core of audience design is that speakers design their style primarily for and in response to their audience. Audience design is generally manifested in a speaker shifting her style to be more like that of the person she is talking to – convergence, in terms of accommodation theory.
4. Audience design applies to all codes and levels of a language repertoire, monolingual and multilingual.
5. Variation on the style dimension within the speech of a single speaker derives from and echoes the variation that exists between speakers on the social dimension. This axiom claims that quantitative style differences are normally less than differences between social groups.
6. Speakers show a fine-grained ability to design their style for a range of different addressees, and to a lessening degree for other audience members such as auditors and overhearers.
7. Style shifts according to topic or setting derive their meaning and direction of shift from the underlying association of topics or settings with typical audience members.
8. As well as the responsive dimension of style, there is the initiative dimension, where a style shift itself initiates a change in the situation rather than results from such a change. Sociolinguists have drawn attention to this distinction at least since Blom and Gumperz's (1972) proposal of situational versus metaphorical styles. In responsive style shift, there is a regular association between language and social situation. Initiative style trades on such associations, infusing the flavor of one setting into a different context, in what Bakhtin (1981) has called 'stylization.' Language becomes an independent variable that shapes the situation.
9. Initiative style shifts are in essence referee design, by which the linguistic features associated with a group can be used to express affiliation with that group. They focus on an absent reference group rather than the present audience. This typically occurs in the performance of a language or variety other than one's own (cf. Rampton's concept of crossing, 1995).

Audience design has been applied in detail as a framework by, for example, Rickford and McNair-Knox (1994) in their study of style shifting by an African American teenager. It has also been contested on a variety of grounds – the priority it gives to social variation over style (Finegan and Biber, 1994), its disregard of the role of attention to speech (Labov, 2001), and in particular, its inadequate attention to the active, constitutive role of language in interaction (Coupland, 2001; Schilling-Estes, 2004). Later developments in audience design (e.g, Bell, 2001) have countered by stressing the proactive nature of language style in identity formation and presentation. Responsive and initiative style are treated as different but concurrent dimensions of language usage, manifesting the structure/agency duality familiar in social theory. This accords both with the stress in contemporary social theory on language as constitutive, and with the dialogical theory of Bakhtin (1981). The range of linguistic analysis in audience design has also been increasingly extended to include qualitative and cooccurrence analyses as well as quantification (Bell, 1999).

The state-of-the-art reader edited by Eckert and Rickford (2001) brings together a wide range of contributions on accommodation theory, audience design, and other sociolinguistic approaches to style. Subsequent work (e.g., Coupland, 2001; Schilling-Estes, 2004) combines strengths from different approaches, including audience design and accommodation theory.

Speech Act Verbs

Definition and Terminology

The term 'speech act verbs' has variously been defined as applying either to all verbs used to refer to any type of verbal behavior or to the much smaller subset of verbs expressing specific speaker attitudes. According to the first, more encompassing definition, verbs such as *to claim*, *to promise*, *to threaten*, *to praise*, *to boast*, *to complain*, *to say*, *to whisper,* and *to interrupt* all count as speech act verbs, whereas the last three of this set are excluded by the second and stricter definition. The terms 'illocutionary verbs,' 'verbs of communication,' and 'verbs of saying,' which have been used as synonyms of 'speech act verbs,' have likewise been defined in either a more or less inclusive fashion. Because verbs such as *to say*, *to whisper*, and *to interrupt* do not lexicalize speaker attitudes, they are semantically less specific than speech act verbs in the narrow sense of the term. For this reason, this contribution is concerned only with speech act verbs that lexicalize combinations of speaker attitudes.

Speech act verbs are used to refer to situations characterized by the following features or situational roles: a speaker (S), a hearer (H), a set of speaker attitudes, and an utterance (Utt) mostly containing a proposition (P). These four elements are part of any situation referred to by speech act verbs and constitute the unifying feature of the meaning of these verbs (Verschueren, 1980: 51–57; 1985: 39–40; Wierzbicka, 1987: 18; Harras *et al.*, 2004: Intro.). They distinguish them from other elements of the lexicon, especially from other types of verbs. Adopting the terminology used by Harras *et al.* (2004) here I call the type of situation referred to by all speech act verbs the 'general

Definition and Terminology

The term 'speech act verbs' has variously been defined as applying either to all verbs used to refer to any type of verbal behavior or to the much smaller subset of verbs expressing specific speaker attitudes. According to the first, more encompassing definition, verbs such as *to claim*, *to promise*, *to threaten*, *to praise*, *to boast*, *to complain*, *to say*, *to whisper,* and *to interrupt* all count as speech act verbs, whereas the last three of this set are excluded by the second and stricter definition. The terms 'illocutionary verbs,' 'verbs of communication,' and 'verbs of saying,' which have been used as synonyms of 'speech act verbs,' have likewise been defined in either a more or less inclusive fashion. Because verbs such as *to say*, *to whisper*, and *to interrupt* do not lexicalize speaker attitudes, they are semantically less specific than speech act verbs in the narrow sense of the term. For this reason, this contribution is concerned only with speech act verbs that lexicalize combinations of speaker attitudes.

Speech act verbs are used to refer to situations characterized by the following features or situational roles: a speaker (S), a hearer (H), a set of speaker attitudes, and an utterance (Utt) mostly containing a proposition (P). These four elements are part of any situation referred to by speech act verbs and constitute the unifying feature of the meaning of these verbs (Verschueren, 1980: 51–57; 1985: 39–40; Wierzbicka, 1987: 18; Harras *et al.*, 2004: Intro.). They distinguish them from other elements of the lexicon, especially from other types of verbs. Adopting the terminology used by Harras *et al.* (2004) here I call the type of situation referred to by all speech act verbs the 'general

resource situation type.' Special types of situations referred to by speech act verbs are called 'special resource situation types.'

Classes of Speech Act Verbs

Special resource situation types constitute the framework for the classification of different types of speech act verbs. They are built up from specifications of the role of the utterance and of the speaker attitudes, which are both elements of the general resource situation type. The set of speaker attitudes may be specified as consisting of the speaker's attitude to the proposition, the speaker's intention, and the speaker's presuppositions. The speaker's propositional attitude may be further specified as S's taking P to be true, S's wanting P, S's evaluating P positively or negatively, and so on. Specifications of the speaker's intention include S's intention to make H believe something or to get him/her to do something. Examples of specifications of the speaker's presuppositions are S's presupposition that H does not know P, that H will do P in the normal course of events, and that H is able to do P. The role of the utterance is specified by properties of the propositional content. These include the event type of P (that is, whether P is an action, event, or state of affairs), the agent of P (in the case that P is an action), and the temporal reference of P (specifically, whether P precedes, coincides with, or follows S's uttering P).

Figure 1 shows the different types of specifications of each of the elements of the general resource situation type. Following a procedure proposed by Baumgärtner (1977: 260–264), the specifications in

Figure 1 Specification of the elements of the general resource situation type.

Figure 1 are obtained from a comparison of sentences containing speech act verbs. The well-formedness of some of these and the ill-formedness of others shows which elements are relevant to the meaning of the verbs they contain. For example, a comparison of the sentences *I order you to leave the room*, **I order you to have left the room*, and **I order you for me to leave the room* shows that *to order* lexicalizes the specification 'future action of H' for the properties of the propositional content.

Different combinations of specifications of the different kinds of speaker attitudes and of the properties of the propositional content constitute special resource situation types, which are referred to by distinct types of speech act verbs. The combinations listed in Table 1 represent situations that are referred to by specific types of verbs. Elements of the situations referred to are also components of the meaning of the corresponding verbs. If the assertives and information verbs in Table 1 are subsumed under the larger class of representatives and verbs expressing emotions are grouped together with those expressing evaluations, all speech act verbs in Table 1 may be classified as belonging to one of four main classes: representatives, directives, commissives, and expressives. These correspond to four of the main types of speech acts distinguished by Searle (1975: 354–361). In addition, there exists a fifth class of verbs that may be used to refer to speech acts, which Searle called 'declarations.' These are speech acts in which a particular institutional fact is brought about by a speaker who has the authority to do so because he or she is a representative of a particular institution. The performance of declarations does not involve any particular speaker attitudes apart from the speaker's being willing to bring about the relevant institutional fact.

Table 1 Classes of speech act verbs

(1a)	**Assertives:** *claim, assert* . . .,	
	Propositional attitude (S):	S takes to be true: P
	Intention (S):	S wants: H recognize: S takes to be true: P
	Presupposition (S):	H does not know: P
	Event type (P):	Action/Event/State of Affairs
	Temporal reference (P):	[-FUTURE]/[+FUTURE]
(1b)	**Information Verbs:** *inform, tell, impart, communicate*, etc.	
	Propositional attitude (S):	S knows: P
	Intention (S):	S wants: H know: P
	Presupposition (S):	H does not know: P
	Event type (P):	Action/Event/State of Affairs
	Temporal reference (P):	[-FUTURE]/[+FUTURE]
(2)	**Directives:** *ask* (*sb. to do sth.*), *order, request* . . . ,	
	Propositional attitude (S):	S wants: P
	Intention (S):	S wants: H do P
	Presupposition (S):	H will not do P in the normal course of events
		H is able to do P
	Event type (P):	Action
	Agent (P):	Hearer
	Temporal reference (P):	[+FUTURE]
(3)	**Commissives:** *promise, guarantee, pledge, vow* . . . ,	
	Propositional attitude (S):	S wants to do P
	Intention (S):	S wants: H recognise: S wants to do P
	Presupposition (S):	P is in the interest of H
	Event type (P):	Action
	Agent (P):	Speaker
	Temporal reference (P):	[+FUTURE]
(4a)	**Verbs Expressing Emotions:** *rejoice, complain, scold* . . . ,	
	Propositional attitude (S):	S feels joy/anger/sorrow because of P
	Intention (S):	S wants: H recognise: S feels joy/anger/sorrow because of P
	Presupposition (S):	P is the case
	Event type (P):	Action/Event/State of Affairs
	Temporal reference (P):	[-FUTURE]
(4b)	**Verbs Expressing Evaluations:** *praise, criticise* . . . ,	
	Propositional attitude (S):	S evaluates P positively/negatively
	Intention (S):	S wants: H recognise: S evaluates P positively/negatively
	Presupposition (S):	P is the case
	Event type (P):	Action
	Agent (P):	Hearer or Third Person
	Temporal reference (P):	[-FUTURE]

Table 2 Different types of classifications of speech acts/speech act verbs

Austin (1962)	*Vendler (1972)*	*Searle (1975)*	*Bach & Harnish (1979)*	*Allan (1994)*
Expositives	Expositives	Representatives	Constatives	Statements

	Exercitives			Authoritatives
Verdictives	Operatives	Declarations	Effectives	
	Verdictives		Verdictives	
Behabitives	Behabitives	Expressives	Acknowledgements	Expressives

Source: Allan (1998: 11).

Accordingly, declaratives, that is verbs used to refer to declarations, differ from other kinds of speech act verbs in that they lexicalize no speaker attitudes other than the speaker's intention to bring about a particular institutional fact. Examples of declaratives include *to absolve*, *to baptize*, *to bequeath*, *to condemn*, *to excommunicate*, *to fire*, *to nominate,* and *to resign*.

Other classifications have much in common with Searle's taxonomy. Austin's (1962: 150–163) classification of speech act verbs, for example, comprises five classes (expositives, exercitives, commissives, behabitives, and verdictives, which approximately correspond to Searle's representatives, directives, commissives, expressives, and declarations, respectively). Vendler's classification was based on Austin's. Due to the fact that Vendler distinguished two types of exercitives (interrogatives and genuine exercitives) as well as two types of verdictives (operatives and true verdictives), his classification consists of seven rather than five classes (Vendler, 1972: 16–25). Bach and Harnish divided speech acts into six general categories. Four of these (constatives, directives, commissives, and acknowledgements) "correspond roughly to Austin's expositives, exercitives, commissives and behabitives respectively, and closely to Searle's representatives, directives, commissives and expressives" (Bach and Harnish, 1979: 40–41). Taken together, the remaining two classes, effectives and verdictives, correspond to what Searle called "declarations." Using H's evaluations as criteria, Allan (1994: 4125; 1998: 10–11) distinguished four types of speech acts. Statements include speech acts such as denials, reports, and predictions (Searle's representatives) as well as promises and offers (Searle's commissives). Invitationals are a subset of Searle's directives and include speech acts such as requests, suggestions, exhortations, and warnings. The rest of Searle's directives are grouped together with his declarations into a class called 'authoritatives.' Expressives, finally, include greetings, thanks, apologies, and congratulations. Table 2 compares the classifications discussed.

Speech Acts and Speech Act Verbs

The examples considered so far suggest that the meanings of speech act verbs may be described in terms of properties of speech acts. The components of speech acts and those of speech act verbs do indeed display substantial overlap. This may be observed from the fact that the components of the meanings of speech act verbs correspond to at least five of the seven components of illocutionary force that serve to determine under which conditions a particular type of speech act is both successful and nondefective (Searle and Vanderveken, 1985: 12–20). These correspondences are summarized in Figure 2.

In spite of these correspondences, special resource situation types do not suffice to capture the meaning of all speech act verbs. Examples of verbs whose meanings cannot completely be described in terms of elements of special resource situation types are *boast*, *flatter,* and *lie*. In addition to the attitudes of a resource situation speaker, these verbs lexicalize different types of evaluations by a speaker who uses these verbs to describe the speech act of the resource situation speaker. Following Barwise and Perry (1983: 32–39), here I call the situation in which a speaker describes an act performed by a resource situation speaker the 'discourse situation.' As Figure 3 shows, the discourse situation comprises the same types of elements as the resource situation: a speaker, a hearer, and an utterance containing a proposition. The meaning of verbs such as *boast*, *flatter,* and *lie* comprises elements of a resource as well as a discourse situation. For example, *boast* lexicalizes not only a positive evaluation of P (one of S's own actions or properties)

Figure 2 Correspondences between components of illocutionary force and components of the meaning of speech act verbs.

by the speaker of the resource situation but also a negative evaluation of the resource situation speaker's positive representation of P by a discourse situation speaker. In particular, a discourse situation speaker describing a resource situation speaker's act of self-praise by means of the verb *boast* thereby indicates that he or she considers the resource situation speaker's positive representation of P to be exaggerated. Similarly, *flatter* and *lie* lexicalize a combination of attitudes of a resource situation speaker as well as a discourse situation speaker's evaluation of the speech act performed by the resource situation speaker as being strategic (*flatter*) or insincere (*lie*). These examples show that for many illocutionary verbs, there is no corresponding speech act. Nor may any type of speech act be referred to by a corresponding illocutionary verb. An example is the apparent lack of a special illocutionary verb in English to refer to an act in which a speaker predicts a future event that he or she considers to have negative consequences. Although there are special illocutionary verbs to describe such acts in German (e.g., *unken*) and Russian (e.g., *karkat*), the relevant act has to be referred to in English by less specific verbs such *predict*, *foretell,* and *prophesy*, whose meanings do not include an evaluative component.

The lack of a one-to-one correspondence of speech acts and speech act verbs also becomes evident from the fact that some verbs are systematically ambiguous among several illocutionary points (Vanderveken, 1990: 168). For example, *to promise* may be used to refer to acts of threatening (as in *I promised him that he would be punished if he did not come back in time*), acts of promising (as in *I promised to help him*), and acts of assuring somebody of something (as in *I promised her that she would be free tomorrow* uttered by a speaker who is not the agent of P but only a confident news bearer). Other examples are *warn* and *advise*, which may both be classified as being either representatives (verbs used to denote an act of telling somebody that something is the case) or directives (verbs used to refer to an act of telling somebody to do something to avoid an imminent danger) (Searle and Vanderveken, 1985: 183). In spite of Austin's claim that speech act verbs are a good guide to speech acts (Austin 1962: 148–149), the absence of a one-to-one correspondence between speech acts and speech act verbs indicates that differences in the meaning of speech act verbs are "a good guide but by no means a sure guide to differences in illocutionary acts" (Searle, 1975: 345).

Performativity

Some speech act verbs can be used not only to denote but also to perform a particular speech act. To test whether a given speech act verb may be used in this way, Austin suggested that it be substituted for the variable *x* in the formula 'I (hereby) x . . .'. Any verb that may be used as a part of this formula may be used performatively (Austin, 1962: 67). Examples of

Figure 3 The inventory of situational roles of the discourse and the resource situation (S_{DS}, discourse situation speaker; S_{RS}, resource situation speaker; P_{DS}, proposition uttered by S_{DS}; P_{RS}, proposition uttered by S_{RS}; H_{DS}, discourse situation hearer; H_{RS}, resource situation hearer). From Harras *et al.* (2004: 10); used with permission of Walter de Gruyter, GmbH. & Co.

performative verbs are *to order*, *to promise*, *to inform*, *to criticize*, and *to assert*. The performative formula is often part of the institutionalized procedure by which a speaker brings about a particular institutional fact. Consequently, declaratives may generally be used performatively as in *I hereby name this ship the* '*Queen Elisabeth*' and *I appoint you chairman*. Other types of speech act verbs can be used performatively only if they may be used in utterances that do not require an additional linguistic or nonlinguistic action for a particular speech act to be performed. For example, a speaker may promise a hearer to help him or her solely by uttering a sentence such as *I promise to help you tomorrow*. By contrast, an act of convincing somebody that something is the case requires more than a speaker's uttering a sentence such as ?*I convince you that Beowulf is the single most important work of English literature*. This difference accounts for the fact that *to promise* may be used performatively, whereas *to convince* may not (Harras 2004: 152–154).

Speech act theory, though foreshadowed by the Austrian philosopher Ludwig Wittgenstein's views about language-games (*see* **Wittgenstein, Ludwig Josef Johann (1889–1951)**), is usually attributed to the Oxford philosopher J. L. Austin (*see* **Austin, John Langshaw (1911–1960)**). The basic ideas, which were formed by him in the late 1930s, were presented in his lectures given at Oxford in 1952–1954, and later in his William James Lectures delivered at Harvard in 1955. These lectures were finally published posthumously as *How to do things with words* in 1962. After his death in 1960, Austin's ideas were refined, systematized, and advanced, especially by his Oxford pupil, the American philosopher John R. Searle. Simply stated, the central tenet of speech act theory is that the uttering of a sentence is, or is part of, an action

performative verbs are *to order*, *to promise*, *to inform*, *to criticize*, and *to assert*. The performative formula is often part of the institutionalized procedure by which a speaker brings about a particular institutional fact. Consequently, declaratives may generally be used performatively as in *I hereby name this ship the* '*Queen Elisabeth*' and *I appoint you chairman*. Other types of speech act verbs can be used performatively only if they may be used in utterances that do not require an additional linguistic or nonlinguistic action for a particular speech act to be performed. For example, a speaker may promise a hearer to help him or her solely by uttering a sentence such as *I promise to help you tomorrow*. By contrast, an act of convincing somebody that something is the case requires more than a speaker's uttering a sentence such as ?*I convince you that Beowulf is the single most important work of English literature*. This difference accounts for the fact that *to promise* may be used performatively, whereas *to convince* may not (Harras 2004: 152–154).

Speech act theory, though foreshadowed by the Austrian philosopher Ludwig Wittgenstein's views about language-games (*see* **Wittgenstein, Ludwig Josef Johann (1889–1951)**), is usually attributed to the Oxford philosopher J. L. Austin (*see* **Austin, John Langshaw (1911–1960)**). The basic ideas, which were formed by him in the late 1930s, were presented in his lectures given at Oxford in 1952–1954, and later in his William James Lectures delivered at Harvard in 1955. These lectures were finally published posthumously as *How to do things with words* in 1962. After his death in 1960, Austin's ideas were refined, systematized, and advanced, especially by his Oxford pupil, the American philosopher John R. Searle. Simply stated, the central tenet of speech act theory is that the uttering of a sentence is, or is part of, an action

within the framework of social institutions and conventions. Put in slogan form, saying is (part of) doing, or words are (part of) deeds.

J. L. Austin

The Performative/Constative Dichotomy

In the 1930s, a very influential school of thought in philosophy was logical positivism, developed by a group of philosophers and mathematicians principally in Vienna. One of the central doctrines of logical positivism is what is now called 'the descriptive fallacy,' namely, the view that the only philosophically interesting function of language is that of making true or false statements. A particular version of the descriptive fallacy is the verificationist thesis of meaning, namely, the idea that 'unless a sentence can, at least in principle, be verified (i.e., tested for its truth or falsity), it was strictly speaking meaningless' (Levinson, 1983: 227). On such a view, sentences that are not used to make verifiable or falsifiable propositions are simply meaningless (*see* **Carnap, Rudolf (1891–1970)**).

It was against this philosophical background that Austin set about to develop his theory of speech acts (Austin, 1962). He made two important observations. First, he noted that some ordinary language sentences such as those in (1) are not employed to make a statement, and as such they cannot be said to be true or false.

(1a) Good afternoon!
(1b) Is he a Republican?
(1c) Come in, please.

Secondly and more importantly, Austin observed that there are ordinary language declarative sentences that similarly resist a truth-conditional analysis. The point of uttering such sentences is not just to say things, but also actively to do things. In other words, such utterances have both a descriptive and an effective aspect. Accordingly, Austin called them 'performatives,' and he distinguished them from assertions, or statement-making utterances, which he called 'constatives.' In other words, performatives are utterances that are used to do things or perform acts, as in (2), whereas constatives are utterances that are employed to makes assertions or statements, as in (3).

(2a) I christen/name this ship the Princess Elizabeth.
(2b) I now pronounce you man/husband and wife.
(2c) I promise to come to your talk tomorrow afternoon.

(3a) My daughter is called Elizabeth.
(3b) A freshly baked loaf doesn't cut easily.
(3c) Maurice Garin won the first Tour de France in 1903.

Unlike those in (3), the declarative sentences in (2) have two characteristics: (i) they are not used intentionally to say anything, true or false, about states of affairs in the outside world, and (ii) their use constitutes (part of) an action, viz., that of christening/naming a ship in (2a), that of pronouncing a couple married in (2b), and that of promising in (2c). In addition, there are two further differences between (2a–b) and (2c). The first is that while (2a–b) is part of a conventional or ritual behavior supported by institutional facts (see also Strawson, 1964), (2c) is not. Secondly, while the performative verb, that is, the verb naming the action while performing it in (2a–b) is in general an essential element and cannot be omitted, it can in (2c). In other words, whereas, for example, we cannot christen/name a ship without using the verb *christen* or *name*, we can make a promise without using the verb *promise*, as in (4).

(4) I'll come to your talk tomorrow afternoon.

Performatives can further be divided into two types: explicit and implicit. Explicit performatives are performative utterances that contain a performative verb that makes explicit what kind of act is being performed. By contrast, implicit performatives are performative utterances in which there is no such verb. Thus, the performatives in (2) are explicit ones, and the performative in (4) is an implicit one.

Austin also isolated a number of syntactic and semantic properties of explicit performatives in English: (i) explicit performatives contain a performative verb, (ii) the performative nature of such a verb can be reinforced by adding the adverb *hereby*, and (iii) explicit performatives occur in sentences with a first-person singular subject of a predicate (verb) in the simple present tense, indicative mood, and active voice.

However, as Austin himself was aware, there are exceptions. Explicit performatives can sometimes take a first-person plural subject, as in (5); a second-person singular or plural subject, as in (6); and a third-person singular or plural subject, as in (7). In addition, there are cases where the explicit performative verb is 'impersonal,' that is, it does not refer to the speaker, as in (8). Furthermore, as (6), (7), and (8) show, explicit performatives can occur in sentences where the verb is in the passive voice. Finally, as (9) indicates, they can also occur in sentences of present progressive aspect.

(5) We suggest that you give up smoking immediately.

(6) You are fired.

(7) Passengers are hereby requested to wear a seat belt.

(8) Notice is hereby given that shoplifters will be prosecuted.

(9) I am warning you not to dance on the table.

Austin's Felicity Conditions on Performatives

As already mentioned, it makes no sense to call a performative true or false. Nevertheless, Austin noticed that for a performative to be successful or 'felicitous,' it must meet a set of conditions. For example, one such condition for the speech act of naming is that the speaker be recognized by his or her community as having the authority to perform that act; for the speech act of ordering, the condition is that the speaker have authority over the addressee; and finally, for the speech act of promising, one condition is that what is promised by the speaker must be something the addressee wants to happen. Austin called these conditions 'felicity conditions,' of which he distinguished three types, as shown in (10).

(10) Austin's felicity conditions on performatives
(10a) (i) There must be a conventional procedure having a conventional effect.
(10a) (ii) The circumstances and persons must be appropriate, as specified in the procedure.
(10b) The procedure must be executed (i) correctly and (ii) completely.
(10c) Often
(i) the persons must have the requisite thoughts, feelings and intentions, as specified in the procedure, and
(ii) if consequent conduct is specified, then the relevant parties must so do.

Violation of any of the conditions in (10) will render a performative 'unhappy' or infelicitous. If conditions *a* or *b* are not observed, then what Austin described as a 'misfire' takes place. For instance, in England, a registrar conducting a marriage ceremony in an unauthorized place will violate condition *a (i)*, thus committing a misfire. The same is true for a clergyman baptizing the wrong baby, because in this case, condition *a (ii)* is not fulfilled. Next, as an illustration of a violation of condition *b (i)*, consider the case of a bridegroom not saying the exact words that are conventionally laid down for a Church of England marriage ceremony. As to condition *b (ii)*, it dictates that the procedure be complete. Thus, in making a bet, the bet is not 'on' unless *You are on* (or something with the same effect) is uttered by the addressee; in Austin's terminology, this counts as a satisfactory 'uptake,' the absence of which will again cause a misfire. Finally, if condition *c* is violated, then what Austin called an 'abuse' is committed (including, but not only, cases of insincerity). Examples include: congratulating someone when one knows that he or she passed his or her examination by cheating (condition *c (i)*); making a promise when one already intends to break it (condition *c (ii)*); and marrying without intending to consummate the marriage (see also Sadock's (2004) discussion of these conditions in terms of misinvocation, misexecution, and abuse).

Locutionary, Illocutionary, and Perlocutionary Speech Acts

The initial distinction made by Austin between performatives and constatives was soon to be rejected by him in favor of a general theory of speech acts. In fact, as pointed by Levinson (1983: 231), there are two internal shifts in Austin's arguments. First, there is a shift from the view that performatives are a special class of sentences/utterances with peculiar syntactic and semantic properties to the view that there is a general class of performatives that encompasses both explicit and implicit performatives, the latter including many other types of sentences/utterances. The second shift is from the performative/constative dichotomy to a general theory of speech acts, of which the various performatives and constatives are just special sub-cases (*see* **Speech Acts and Grammar**).

What led Austin to abandon the performative/constative dichotomy? In the first place, he noted that like performatives, constatives are also subject to the felicity conditions stated in (10). Consider the so-called 'Moore's paradox,' illustrated by (11).

(11) ?Princess Diana died in a fatal car crash in Paris with Dodi Al Fayed, but I don't believe it.

This utterance is infelicitous because it violates condition *c (i)* in (10) above. In the same vein, if someone utters (12) when he or she knows that John does not in fact have a wife, then its presupposition will not go through (*see* **Presupposition**). The reason the presupposition fails to carry through is that condition *a (ii)* in (10) above is not adhered to.

(12) I'm sure John's wife is a feminist.

Secondly, Austin observed that performatives and constatives may be impossible to distinguish even in truth-conditional terms. On the one hand, there are 'loose' constatives that may not be assessed strictly by means of truth conditions, as in (13). On the other hand, there are utterances like those in (14) that pass the *hereby* test and therefore are performatives by definition but that nevertheless are used to state or assert. In these cases, the performatives must be counted simultaneously as constatives. On the basis of such evidence, Austin concluded that constatives are nothing but a special class of performatives, and

that the two-way distinction between performatives, as action-performers, and constatives, as truth-bearers, can no longer be maintained.

(13a) France is hexagonal.
(13b) The fridge is empty.
(13c) New York is sixty miles from where I live.

(14a) I hereby state that Da Vinci started to paint *Mona Lisa* in 1503.
(14b) I hereby tell you that the bill is right.
(14c) I hereby hypothesize that there is water on Mars.

Consequently, Austin claimed that all utterances, in addition to meaning whatever they mean, perform specific acts via the specific communicative force of an utterance. Furthermore, he introduced a three-fold distinction among the acts one simultaneously performs when saying something, as illustrated in (15):

(15) (A speech act's three facets)
(i) Locutionary act: the production of a meaningful linguistic expression.
(ii) Illocutionary act: the action intended to be performed by a speaker in uttering a linguistic expression, by virtue of the conventional force associated with it, either explicitly or implicitly.
(iii) Perlocutionary act: the bringing about of consequences or effects on the audience through the uttering of a linguistic expression, such consequences or effects being special to the circumstances of utterance.

A locutionary act is the basic act of speaking, which itself consists of three related sub-acts: (i) a phonic act of producing an utterance-inscription; (ii) a phatic act of composing a particular linguistic expression in a particular language; and (iii) a rhetic act of contextualizing the utterance-inscription (Austin, 1962). The first of these three sub-acts is concerned with the physical act of producing a certain sequence of vocal sounds (in the case of spoken language), or a set of written symbols (in the case of written language). The second refers to the act of constructing a well-formed string of sounds/symbols (a word, phrase, or sentence in a particular language). The third sub-act is responsible for tasks such as assigning reference, resolving deixis, and disambiguating the utterance-inscription lexically and/or grammatically (*see* **Deixis and Anaphora: Pragmatic Approaches**).

The illocutionary act refers to the fact that when we say something, we usually say it with some purpose in mind. In other words, an illocutionary act refers to the type of function the speaker intends to fulfill, or the action the speaker intends to accomplish in the course of producing an utterance; it is also an act defined within a system of social conventions. In short, it is an act accomplished in speaking. Examples of illocutionary acts include accusing, apologizing, blaming, congratulating, declaring war, giving permission, joking, marrying, nagging, naming, promising, ordering, refusing, swearing, and thanking. The functions or actions just mentioned are also commonly referred to as the illocutionary 'force' (or 'point') of the utterance. Illocutionary force is frequently conveyed by what Searle (1969) called an 'illocutionary force indicating device' (IFID), the most direct and conventional type of which is an explicit performative in the form of (16) (where Vp stands for performative verb). Indeed, the term 'speech act' in its narrow sense is often taken to refer exclusively to illocutionary acts (*see* **Speech Acts: Definition and Classification**).

(16) I (hereby) Vp you (that) S

It should be mentioned at this point that the same linguistic expression can be used to carry out a wide variety of different speech acts, so that the same locutionary act can count as having different illocutionary forces in different contexts. Depending on the circumstances, one may utter (17) to make a threat, to issue a warning, or to give an explanation.

(17) The gun is loaded.

In fact, Alston (1994) has argued that the meaning of a sentence consists in its having a certain illocutionary act potential (IAP) that is closely and conventionally associated with its form. On this view, to know what a sentence means is to know what range of illocutionary acts it can be conventionally used to perform.

Conversely, the same speech act can be performed by different linguistic expressions, or the same illocutionary force can be realized by means of different locutionary acts. The utterances in (18), for example, illustrate different ways of carrying out the same speech act of requesting.

(18) (At ticket office in railway station)
(18a) A day return ticket to Oxford, please.
(18b) Can I have a day return ticket to Oxford, please?
(18c) I'd like a day return ticket to Oxford.

Finally, a perlocutionary act concerns the effect an utterance may have on the addressee. Put slightly more technically, a perlocution is the act by which the illocution produces a certain effect in or exerts a certain influence on the addressee. Still another way to put it is that a perlocutionary act represents a consequence or by-product of speaking, whether intentional or not. The effect of the act being performed by speaking is generally known as the perlocutionary effect. There is

an extensive literature on the differentiation between locutionary, illocutionary, and perlocutionary acts (see e.g., Sadock (2004) for a survey).

J. R. Searle

Searle's Felicity Conditions on Speech Acts

Just as its truth conditions must be met by the world for a sentence to be said to be true, its felicity conditions must also be fulfilled by the world for a speech act to be said to be felicitous. Searle (1969) took the view that the felicity conditions put forward by Austin are not only ways in which a speech act can be appropriate or inappropriate, but that they also jointly constitute the illocutionary force. Put in a different way, the felicity conditions are the constitutive rules – rules that create the activity itself – of speech acts (*see* **Principles and Rules**). On Searle's view, to perform a speech act is to obey certain conventional rules that are constitutive of that type of act. Searle developed the original Austinian felicity conditions into a neo-Austinian classification of four basic categories, namely (i) propositional content, (ii) preparatory condition, (iii) sincerity condition, and (iv) essential condition. As an illustration of these conditions, consider (19).

(19) Searle's felicity conditions for promising
(i) propositional content: future act A of S
(ii) preparatory: (a) H would prefer S's doing A to his not doing A, and S so believes
(b) It is not obvious to both S and H that S will do A in the normal course of events
(iii) sincerity: S intends to do A
(iv) essential: the utterance of e counts as an undertaking to do A

where S stands for the speaker, H for the hearer, A for the action, and e for the linguistic expression.

The propositional content condition is in essence concerned with what the speech act is about. That is, it has to do with specifying the restrictions on the content of what remains as the 'core' of the utterance (i.e., Searle's propositional act) after the illocutionary act part is removed. For a promise, the propositional content is to predicate some future act of the speaker, whereas the preparatory conditions state the real-world prerequisites for the speech act. In the case of a promise, the latter are roughly that the addressee would prefer the promised action to be accomplished, that the speaker knows this, but also that it is clear to both the speaker and the addressee that what is promised will not happen in the normal course of action. Next, the sincerity condition must be satisfied if the act is to be performed sincerely. When carrying out an act of promising, the speaker must genuinely intend to keep the promise. Notice that if the sincerity condition is not fulfilled, the act is still performed, but there is an abuse, to use Austin's term. Finally, the essential condition defines the act being performed in the sense that the speaker has the intention that his or her utterance will count as an act, and that this intention is recognized by the addressee. Thus for a promise, the speaker must have the intention to create an obligation to act. Failure to meet the essential condition has the consequence that the act has not been carried out.

Searle's Typology of Speech Acts

Can speech acts be classified, and if so, how? Austin (1962) grouped them into five types: (i) verdictives: giving a verdict, (ii) exercitives: exercising power, rights or influence, (iii) commissives: promising or otherwise undertaking, (iv) behabitives: showing attitudes and social behavior, and (v) expositives: fitting an utterance into the course of an argument or conversation. Since then, there have been many attempts to systematize, strengthen, and develop the original Austinian taxonomy (Bach and Harnish, 1979; Allan, 2001; Bach, 2004). Some of these new classifications are formulated in formal/grammatical terms, others, in semantic/pragmatic terms, and still others, on the basis of the combined formal/grammatical and semantic/pragmatic modes (see Sadock (2004) for a review) (*see* **Speech Acts: Definition and Classification**; **Pragmatics: Overview**). Of all these (older and newer) schemes, Searle's (1975a) neo-Austinian typology remains the most influential. Under Searle's taxonomy, speech acts are universally grouped into five types along four dimensions: (i) illocutionary point, (ii) direction of fit between words and world, (iii) expressed psychological state, and (iv) propositional content (see also Searle (2002)). The five types of speech acts are further explained next.

(i) Representatives (or assertives; the constatives of the original Austinian performative/constative dichotomy) are those kinds of speech acts that commit the speaker to the truth of the expressed proposition and thus carry a truth-value. They express the speaker's belief. Paradigmatic cases include asserting, claiming, concluding, reporting, and stating. In performing this type of speech act, the speaker represents the world as he or she believes it is, thus making the words fit the world of belief.

(20) The Berlin Wall came down in 1989.

(ii) Directives are those kinds of speech acts that represent attempts by the speaker to get the addressee to do something. They express the speaker's desire/wish for the addressee to do something. Paradigmatic

cases include advice, commands, orders, questions, and requests. In using a directive, the speaker intends to elicit some future course of action on the part of the addressee, thus making the world match the words via the addressee.

(21) Put the cake in the oven.

(iii) Commissives are those kinds of speech acts that commit the speaker to some future course of action. They express the speaker's intention to do something. Paradigmatic cases include offers, pledges, promises, refusals, and threats. In the case of a commissive, the world is adapted to the words via the speaker himherself.

(22) I'll never buy you another computer game.

(iv) Expressives are those kinds of speech acts that express a psychological attitude or state of the speaker such as joy, sorrow, and likes/dislikes. Paradigmatic cases include apologizing, blaming, congratulating, praising, and thanking. There is no direction of fit for this type of speech act.

(23) Well done, Elizabeth!

(v) Declarations (or declaratives) are those kinds of speech acts that effect immediate changes in some current state of affairs. Because they tend to rely on elaborate extralinguistic institutions for their successful performance, they may be called institutionalized performatives. In performing this type of speech act, the speaker brings about changes in the world; that is, he or she effects a correspondence between the propositional content and the world. Paradigmatic cases include (officially) opening a bridge, declaring war, excommunicating, firing from employment, and nominating a candidate. As to the direction of fit, it is both words-to-world and world-to-words.

(24) I object, Your Honor.

Illocutional point (or speech act type), direction of fit, and expressed psychological state can be summarized as in (25).

(25)

Illocutionary point/Speech act type	Direction of fit	Expressed psychological state
representative	words-to-world	belief
directive	world-to-words	desire
commissive	world-to-words	intension
expressive	none	variable
declaration	both	none

Indirect Speech Acts

What is an indirect speech act? Most of the world's languages have three basic sentence types: declarative, interrogative, and imperative. In some languages, the three major sentence types are distinguished morphologically and/or syntactically; as instances, compare Somali, Greenlandic, or Lakhota (Lakota) (see Huang (2006) for further discussion). The three sentence types are typically associated with the three basic illocutionary forces, namely, asserting/stating, asking/questioning, and ordering/requesting, respectively.

In the case of a direct match between a sentence type and an illocutionary force, we have a direct speech act. In addition, explicit performatives, which happen to be in the declarative form, are also taken to be direct speech acts, because they have their illocutionary force explicitly named by the performative verb in the main part (or 'matrix clause') of the sentence. On the other hand, if there is no direct relationship between a sentence type and an illocutionary force, we are faced with an indirect speech act. Thus, when an explicit performative is used to make a request, as in (26), it functions as a direct speech act; the same is the case when an imperative is employed, as in (27). By comparison, when an interrogative is used to make a request, as in (28), we have an indirect speech act.

(26) I request you to pass the salt.

(27) Pass the salt.

(28) Can you pass the salt?

In short, the validity of the distinction between direct and indirect speech acts is dependent upon whether or not one subscribes to what Levinson (1983: 264, 274) has called the 'literal force hypothesis' – the view that there is a direct structure-function correlation in speech acts and that sentence forms are direct reflexes of their underlying illocutionary forces.

There are, however, problems at the very heart of the literal force hypothesis. One is that there are cases of speech acts where even the direct link between performative verbs and speech acts breaks down. Consider (29).

(29) I promise to sack you if you don't finish the job by this weekend.

In (29), the performative verb is *promise*, but the force that is most naturally ascribed to this speech act is that of either a threat or a warning. This shows that, contrary to the literal force hypothesis, we cannot always identify speech acts, even with sentences containing a performative verb.

Secondly and more importantly, as also pointed out by Levinson (1983: 264), most usages are indirect. The speech act of requesting, for example, is very rarely performed by means of an imperative in English. Instead, it is standardly carried out indirectly.

Furthermore, there are probably infinitely many varieties of sentences that can be used to indirectly make a request, as shown in (30).

(30a) I want you to put the cake in the oven.
(30b) Can you put the cake in the oven?
(30c) Will you put the cake in the oven?
(30d) Would you put the cake in the oven?
(30e) Would you mind putting the cake in the oven?
(30f) You ought to put the cake in the oven.
(30g) May I ask you to put the cake in the oven?
(30h) I wonder if you'd mind putting the cake in the oven?

As to how to analyze indirect speech acts, there are roughly three approaches. The first is to assume the existence of a dual illocutionary force (as proposed by Searle, 1975b). On this assumption, indirect speech acts have two illocutionary forces, one literal or direct, and the other nonliteral or indirect. While the literal force is secondary, the nonliteral force is primary. Next, whether an utterance operates as an indirect speech act or not has to do with the relevant felicity conditions. For example, (28) both infringes the felicity condition for a question and queries the preparatory condition for a request. This explains why it can function as an indirect speech act, whereas (31), for instance, cannot; the reason is that in the case of (31), felicity conditions are irrelevant.

(31) Salt is made of sodium chloride.

Finally, on Searle's view, because a speaker's performing and an addressee's understanding an indirect speech act always involves some kind of inference, the question is how this inference can be computed. Searle's suggestion is that it can be computed along the general lines of the rational, cooperative model of communication articulated by Grice (1989) (*see* **Inference: Abduction, Induction, Deduction**; **Grice, Herbert Paul (1913–1988)**; **Cooperative Principle**).

One interesting characteristic of indirect speech acts is that they are frequently conventionalized (see, e.g., Morgan, 1978). This can be illustrated by the fact that of various, apparently synonymous linguistic expressions, only one may conventionally be used to convey an indirect speech act, as illustrated in (32).

(32a) Are you able to pass the salt?
(32b) Do you have the ability to pass the salt?

Under Searle's analysis, both (32a) and (32b) would be expected to be able to perform the indirect speech act of requesting, because (i) they are largely synonymous with (28), and (ii) they, too, inquire about the satisfaction of the addressee-based preparatory condition for making a request. But this expectation is not fulfilled.

Searle's response to this puzzle is that there is also a certain degree of conventionality about indirect speech acts, and that this may be accounted for in terms of conventions of meaning/usage. Inspired by this insight, Morgan (1978) developed the notion of 'short-circuited implicature' to cover inference involved in cases like (28) (*see* **Implicature**). While the relevant implicature is in principle calculable, in practice it is not calculated in cases like these. From a linguistic point of view, the conventionality here is correlated with the possible occurrence of *please*. While *please* can be inserted before the verb *pass* in (26)–(28), it cannot in (32), as shown in (33).

(33a) I request you to please pass the salt.
(33b) Please pass the salt.
(33c) Can you please pass the salt?
(33d) ?Are you able to please pass the salt?
(33e) ?Do you have the ability to please pass the salt?

Furthermore, the conventionality indicated by *please* in (33a) and (33b) is one of meaning, hence the speech act of requesting is performed directly. By contrast, the conventionality signaled by *please* in (33c) is one of usage, and thus we have an indirect speech act.

A second, rather similar, approach is due to Gordon and Lakoff (1975). In their analysis, there are inference rules called 'conversational postulates' that reduce the amount of inference needed to interpret an indirect speech act. Thus, in the case of (28), if the interpretation as a question cannot be intended by the speaker, then the utterance will be read as being equivalent to his or her having said (26), thus resulting in the performance of the indirect speech act of requesting. Stated this way, the conversational postulates proposed by Gordon and Lakoff can be seen as another reflection of the conventionality of indirect speech acts. As to the similarities and differences between Searle's and Gordon and Lakoff's analyses, the major similarity is that both accounts assume that the interpretation of indirect speech acts involves inference as well as conventionality; the major difference concerns the question of balance, namely, how much of the work involved in computing an indirect speech act is inferential and how much is conventional.

Finally, in contrast to the inferential models we have just discussed, there is the idiom model. In this model, sentences like (28) are semantically ambiguous, and the request interpretation constitutes a speech act idiom that involves no inference at all. On this view, (28) is simply recognized as a request, with no question being perceived. This is the position taken by Sadock (1974). There are, however, problems with this analysis, too. One is that it fails to

capture the fact that (in contrast to what is the case for idioms) the meaning of an indirect speech act can frequently (at least in part) be derived from the meaning of its components (the technical term for this is 'compositionality'; *see* **Frege, Gottlob (1848–1925)**); in addition, these would-be 'idioms' turn out to be quite comparable cross-linguistically (something which idioms are not). For example, an utterance like (34) may be used, with the same force as in English, in its Arabic, Chinese, German, or Modern Greek versions to indirectly request the addressee to switch on the central heating system (of course, always depending on the context).

(34) 'It's cold in here.'

A further problem is that in the idiom model, an interpretation that takes into account the literal meaning or the direct illocutionary force of an indirect speech act is not allowed. This, however, leaves examples like (35) unexplained.

(35) A: Can you pass the salt?
B: Yes, I can. (Here it is.)

Why, then, do people use indirect speech acts? One answer is that the use of indirect speech acts is in general associated with politeness. Indirect speech acts are usually considered to be more polite than their direct counterparts (see the considerable literature on the analysis of speech acts, especially the work on face-threatening acts (FTAs) like requests, complaints, and apologies in the tradition of Brown and Levinson's (1987) classical 'face-saving' politeness model *see* **Face**; **Politeness**; **Pragmatic Acts**).

Speech Acts and Culture

Cross-Cultural Variation

Many speech acts are culture-specific. This is particularly so in the case of institutionalized speech acts, which typically use standardized and stereotyped formulae and are performed in public ceremonies. A good example is provided by the speech act of divorcing. In some Muslim cultures, under the appropriate circumstances, the uttering of a sentence with the import of (36) three times consecutively by a husband to his wife will *ipso facto* constitute a divorce. By contrast, in Western cultures, no one (no matter what his or her religion is) can felicitously use (36) to obtain a divorce.

(36) 'I hereby divorce you.'

But how about non-institutionalized speech acts? First of all, as said above, any given speech act may be culture-specific. Rosaldo (1982), for example, observed that the speech act of promising has no place among the Ilongots – a tribal group of hunters and horticulturalists in the Philippines. She attributes the absence of this speech act in the conceptual repertoire of the Ilongot to a lack of interest in sincerity and truth in that community. The Ilongot, argues Rosaldo, are more concerned with social relationships than with personal intentions. On the basis of anthropological evidence such as this, Rosaldo claims that the universality of Searle's typology of speech acts cannot be maintained. Another example of this kind has been reported for the Australian aboriginal language Yolngu. According to Harris (1984: 134–135), there does not seem to be any speech act of thanking in the Yolngu speaker's repertoire.

Conversely, a given speech act may be present only in certain cultures. For example, in the Australian aboriginal language Walmajari, one finds a speech act of requesting that is based on kinship rights and obligations. The verb in question is *japirlyung* (Hudson, 1985), and the speech act may be called 'kinship-based requesting,' because it conveys a message meaning roughly 'I ask/request you to do X for me, and I expect you to do it simply because of how you are related to me'. Thus, for the speakers of Walmajari, it is very difficult to refuse a kinship-based speech act of requesting (see also Wierzbicka, 1991: 159–160). 'Exotic' speech acts such as the kinship-based requesting do not seem to be present in other East Asian or Western cultures.

Secondly, given a particular situation, pertinent speech acts are carried out differently in different cultures. For instance, in some East Asian and Western cultures, if one steps on another person's toes, one normally performs the speech act of apologizing. But apparently this is not the case among the Akans, a West African culture. As reported by Mey (2001: 287, crediting Felix Ameka), in that culture, such a situation does not call for apologies but calls for the expression of sympathy: "The focus is on the person to whom the bad thing has happened rather than the person who has caused the bad thing" (Mey, 2001: 287). Another example: while in English, thanks and compliments are usually offered to the hosts when leaving a dinner party, in Japanese society, apologies such as *o-jama itashimashita* 'I have intruded on you' are more likely to be offered by the guests. A similar speech act of apologizing is performed in Japanese upon receiving a present, when a Japanese speaker is likely to say something like *sumimasen* – the most common Japanese 'apology' formula or one of its variants. Conversely (as pointed out by many authors), apologies can be used in a much broader range of speech situations in Japanese than in English.

Thirdly, in different cultures/languages, the same speech act may meet with different typical responses. For example, a compliment normally generates acceptance/thanking in English, but self-denigration in Chinese, Japanese, or even Polish. A typical compliment/response formula in Chinese would be something like (37).

(37) A: ni cai zuode zhen hao!
B: nali, nali, wo bu hui zuocai.
A: bie keqi. ni cai zhende zuode hen hao!
B: ni tai keqi le.
A: 'You cook really well!'
B: 'No, no, I don't really know how to cook properly.'
A: 'Please don't be too modest. You really cook very well.'
B: 'You're too kind.'

The same is even more true in Japanese. According to Mizutani and Mizutani (1987: 43), "[T]he Japanese will never accept a compliment without saying *iie* ['no']". Given the general Japanese reluctance to say 'no' under almost any other circumstances, the compliment response pattern is rather striking.

Fourthly, the same speech act may differ in its directness/indirectness in different cultures. Since the late 1970s, a great deal of research has been conducted on how particular kinds of speech acts, especially such face-threatening acts as requests, apologies, and complaints are realized across different languages (*see* **Face**). Of these investigations, the most influential is the large-scale Cross-Cultural Speech Act Realization Patterns Project (CCSARP) (Blum-Kulka *et al.*, 1989). In this project, the realization patterns of requesting and apologizing in German; Hebrew; Danish; Canadian French; Argentinean Spanish; and British, American, and Australian English were compared and contrasted. In the case of requests, the findings were that among the languages examined, the Argentinean Spanish speakers are the most direct, followed by the speakers of Hebrew. The least direct are the Australian English speakers, while the speakers of Canadian French and German are positioned at the midpoint of the directness/indirectness continuum. Building on the CCSARP, strategies for the performance of certain types of face-threatening acts in a much wider range of languages have since been examined. These languages include Catalan, Chinese, Danish, Dutch, French, German, Greek, Hebrew, Japanese, Javanese, Polish, Russian, Thai, Turkish, four varieties of English (British, American, Australian, and New Zealand), two varieties of French (Canadian and French), and eight varieties of Spanish (Argentinean, Ecuadorian, Mexican, Peninsular, Peruvian, Puerto Rican, Uruguayan, and Venezuelan). As a result of these studies, it has now been established that there is indeed extensive cross-cultural variation in directness/indirectness in speech acting, especially in the realization of face-threatening acts (FTAs), and that these differences are generally associated with the different means that different languages utilize to realize speech acts (*see* **Intercultural Pragmatics and Communication**). These findings have undoubtedly contributed to our better understanding of cross-cultural/linguistic similarities and differences in face-redressive strategies for FTAs (see Huang (2006) for detailed discussion).

Interlanguage Variation

A number of studies have recently appeared that explore speech acts in interlanguage pragmatics. Simply put, an interlanguage is a stage on a continuum within a rule-governed language system that is developed by L2 learners on the way to acquiring the target language. This language system is intermediate between the learner's native language and his or her target language (*see* **Variation in Second Language Acquisition**).

Some of these studies investigate how a particular type of speech act is performed by non-native speakers in a given interlanguage; others compare and contrast the similarities and differences in the realization patterns of given speech acts between native and non-native speakers of a particular language. The best studied interlanguage is that developed by speakers of English as a second language. Other interlanguages that have been investigated include Chinese, German, Hebrew, Japanese, and Spanish (see Huang (2006) for further discussion).

A few recent formal and computational approaches to speech acts and speech act theory are worthy of note. One important theoretical development is the integration of speech acts with intensional logic, resulting in what is called 'illocutionary logic' (Searle and Vanderveken, 1985; Vanderveken, 1994, 2002). Similarly, Merin (1994) has endeavored to produce an algebra of what he calls 'social acts.' Finally, recent formalizations of various aspects of speech act theory in artificial intelligence and computational linguistics can be found in Perrault (1990), Bunt and Black (2000), and Jurafsky (2004) (see also Sadock, 2004).

Language and Action

Language is complicated. The scope of the current encyclopedia shows that clearly enough – if you read all the thousands of articles in this encyclopedia you still won't really know how language works.

Attempts to write computer systems that can process language simply emphasize this point. To write a computer system that can analyze or generate unrestricted natural language requires a collection of complex algorithms and data structures – speech recognizers and generators, lexica, sets of morphological and morphophonemic rules, grammars, parsers, logical form builders, inference engines – linked to vast amounts of background knowledge. To make matters worse, all of this knowledge has to be deployed in ways that make it robust when speakers or writers defy the conventional rules of their language. Language is complicated, and building computer systems that can understand and produce it is difficult.

If language is so complex, why do we use it? Because it is an extremely efficient way of getting information from one person to another, and in particular because it is an extremely efficient way of getting someone else to do what you want (or at any rate, of getting them to know what you want them to do: getting them to actually do it is yet another step). Since most human beings do not appear to possess telepathic powers, we cannot have direct access to what someone else believes, knows or wants, so making someone else aware of what we want is extremely challenging. The ability to convey new concepts by extending our vocabulary, and to produce new combinations of concepts at will simply by using new combinations of words, mean that we can use language to convey almost any wish that we can conceive of.

Getting someone else to understand what you want them to do is extremely valuable, since if they know what you want them to do, there is a reasonable chance that they will do it – certainly more chance than if they **don't** know what you want. So language provides devices for letting other people know what you want.

English, for instance, makes a distinction between assertions, which are normally used for conveying what you want your hearer to believe some proposition; questions, which are used to indicate that you want your hearer to provide you with information that you lack; and commands, which directly denote actions that you would like the hearer to carry out.

Assertions, questions, and commands have characteristic surface properties. Simple English questions, for instance, conform to a pattern where the utterance starts with an auxiliary verb, followed by the subject and then the remainder of the sentence. Other languages employ other markers, but most languages have some sort of surface marker for distinguishing between the utterance types. Working out what the speaker wants, then, should just be a matter of spotting and interpreting the surface markers.

The situation is, however, more complicated than that. People use utterances which look like questions to make statements or request actions (1); they use utterances that look like assertions to seek information or to request actions (2); and they use utterances that look like commands to seek information or, more infrequently, to make statements (3):

(1a) Do you know what time it is? (uttered standing underneath the station clock ≈ You're late)
(1b) Could you make me a cup of cocoa? (≈ Please make me a cup of cocoa)

(2a) I don't know where the milk is (≈ Please tell me where the milk is)
(2b) The door's open (uttered when someone has knocked ≈ Come in)

(3a) Tell me where the cocoa powder is kept.
(3b) Just accept that I'm right and you're wrong (≈ I'm right and and you're wrong)

Searle (1969), following suggestions by Austin (1962), introduced the notion of speech acts to explain that the production of utterances in appropriate circumstances can have 'real world' consequences. In some cases, Searle's speech acts have an effect on the external world simply by being performed. If a registrar says, at the end of a properly conducted ceremony, 'I now pronounce you man and wife,' then from that moment on those two people **are** man and wife: performing the linguistic action has actually changed the world. If you say 'I promise to do the washing up,' then from that moment on you are under an obligation to do the washing up. Simply performing the act transforms the world in ways that go beyond just changing the information that is available to the hearer.

In most cases, however, one cannot work out the ramifications of producing an utterance unless a great deal is known about the context in which it is produced. In particular, one may have to know about what the speaker knows and believes about the world in general, and about what they know and believe about the hearer's knowledge and beliefs

(including the hearer's knowledge and beliefs about the speaker's knowledge and beliefs, and . . .), as well as about the speaker's likely goals in the current situation. It seems, then, that if you want to build a computer system that can take part in an unrestricted dialogue with a human, you will have to provide it with the ability to reason about actions, knowledge, and beliefs.

Artificial Intelligence Planning Theory

How important is for a computer system that can take part in unrestricted dialogues to be able to handle cases (1–3)? If people don't actually produce utterances like these very often, then maybe there is no need to equip systems with the ability to handle them.

In order to find out how important it is for a system to be able to cope with particular phenomena, system designers often carry out 'Wizard of Oz' (WoZ) experiments to find out what users actually want to do. It is worth investigating whether it is always clear what a user means by every utterance they produce. If it is, then at least for practical dialogue systems there is no need to worry about the issues raised by (1–3).

In a WoZ experiment the experimental subject has access to input and output devices (keyboard and screen, microphone and speakers . . .) which are apparently connected to a software system that can carry out some task. The subject asks questions, and the system responds appropriately. By keeping a transcript of the dialogue between the subject and the system, you can obtain a great deal of information about user behavior: what sort of language they use, what sort of tasks they try to perform, what sort of information they want, and so on.

Of course, if you do the experiment **before** you build your program then there cannot be a system that carries out the task. Instead there is an experimenter who has access to the information that the desired system would have provided. The experimenter responds to the user by filling in slots in canned phrases, which are then typically played back to the user via a text-to-speech system to preserve the illusion that the response is being provided by a software system.

The point of such experiments is to find out how users would interact with an ideal system. If you know what your users would really like, you know what you have to aim for.

WoZ experiments consistently show that people habitually use **indirect** constructions when seeking information. We say 'Do you know when the next train to Buxton is?' to mean 'When is the next train to Buxton?'; we say 'Can you tell me which platform it goes from?' to mean 'Which platform does it go from?'; and so on.

We will return to **why** people use such circumlocutions below. The first task is to work out how you could produce a computational system that could spot that someone who says 'Do you know the time?' may be interested less in whether you know the time than in what the time is (though note that there are circumstances in which a question like this may be intended to mean exactly what its face value indicates, so you cannot just introduce a set of one-to-one translations).

The key observation in computational work in this area is that Searle's description of speech acts looks rather like the way actions are represented in planning theory in artificial intelligence (AI) (Cohen and Perrault, 1979; Allen and Perrault, 1980; Cohen and Levesque, 1980). Given that what is needed is a way to link linguistic actions to external actions in order to achieve what the speaker actually wants, and that AI planning theory provides a way of stringing external actions together to achieve specified goals, the idea of using existing approaches to planning in order to handle speech acts is very tempting.

The STRIPS Formalism

The approach to planning that underpinned early AI work on speech acts arose from attempts to enable robots to make plans by building sequences of basic actions in order to achieve complex goals. This work is usually illustrated by 'blocks world' examples – examples involving a robot with a single 'hand' which can be moved around until it is over a desired point in the work space, raised or lowered, and opened or closed. The reason for concentrating on this domain is that it is simple enough to support experiments using different planning algorithms, but also rich enough to illustrate most of the problems that arise in more complex domains.

Early AI work on planning starts from the observation that actions involve relations between situations (Fikes and Nilsson, 1971; Hart *et al.*, 1972). If you want to make a plan out of primitive actions, then there are two things you need to know about each possible action: under what circumstances it can be performed, and in what ways it changes the world. These are not the only things that matter – you might, for instance, be concerned about how long an action takes, or what resources it consumes – but they are the key issues.

Fikes and Nilsson (1971) presented a representation language for describing actions and an algorithm for constructing sequences of actions to achieve

specified sets of goals. The original presentation of the STRIPS (Stanford Research Institute Problem Solver) formalism was fairly dense, but the essence is captured by saying that what matters about an action is the conditions under which it can be performed (its preconditions) and the propositions that it makes true (its effects). The original STRIPS notation divided the effects into an add list of propositions that will become true after the action is performed and a delete list of propositions that will become false. This division becomes rather awkward when you try to apply this framework to speech acts, so in this article we will simply talk about the effects, some of which may be negated. It turns out that adding a set of 'subactions' which specify how you actually carry out this action is useful, e.g., that in order to grasp something you have to run the motor that controls the gripper. This was not present in the standard formulation of the STRIPS schemata, but is crucial when you try to apply AI planning theory to linguistic action, so the initial presentation of this work will include it.

A typical blocks world action, for instance, might look as follows:

action(*grasp*(*X*),
  preconditions([*handEmpty*, *clear*(*X*),
    on(*X*, *Y*)]),
  effects([*holding*(*X*), *clear*(*Y*), *not*(*handEmpty*),
    not(*on*(*X*, *Y*))]),
  subActions([*close*(*switch*17)])

This action schema says that (i) you can grasp an object X if your hand is empty, X is clear, and it is resting on some other object Y; (ii) once you have grasped X then you will be holding X, and Y will be clear, and your hand will no longer be empty, and X will no longer be on Y; and (iii) the way to perform a grasping action is to turn on the relevant motor when you are in the right position.

This representation of grasping is very rough. The assumption that as soon as you grasp something you have taken its weight, so that it is no longer resting on the surface where it was when you grasped it, is open to debate. The need for dual terms is irritating (why are *handEmpty* and *holding*(*X*) both required? Surely my hand is empty precisely when I am not holding anything). Nonetheless, this approach to action descriptions has been at the core of nearly all approaches to planning since the original papers about STRIPS.

Given a set of action schemata of this kind, there are a number of ways of constructing sequences of actions that will transform an initial state of affairs so that it matches some specified set of goals. We will examine two of these ways here, the 'state space search' and the 'plan space search.'

In the state space search, you may decide to construct a plan by trying different actions and examining the different states of affairs that they lead to. This approach, which was taken in most early work on planning, is known as 'state space search' because it involves looking at the different states that would be produced by various partial plans.

There are two basic strategies for carrying out state space planning:

- Backward chaining: You can look for an action *A* whose effects contain something that matches one of your goals *G*. If you could perform this action, then *G* would become true, so this looks like a good candidate as part of a plan for achieving at least one of your current goals. Unfortunately, it may not be possible to perform *A* in the current situation, because one or more of its preconditions may not be satisfied. But if you add the currently unsatisfied preconditions to the set of open goals, then you may be able to find actions which would achieve them and hence allow you to perform *A*, and achieve *G*.
- Forward chaining: You can look for an action *A* which is performable in the current situation, and see whether the result of performing it would be any better. You may have some measure of whether you are getting closer to your goals, or you may do this blindly, just trying things out at random to see what happens.

Backward chaining seems, at first sight, to be more sensible, since it involves looking for actions that can be seen to have some direct connection with the desired outcomes. There are, however, many situations in which backward chaining fails, and there is a substantial literature on techniques for combining the best of both strategies, and for avoiding the problems that arise with simple-minded backward chaining.

Recent work on planning in robotics domains takes a slightly different approach, the plan space search (Blum and Furst, 1997; Kambhampati, 1997; Bonet and Geffner, 2001). Instead of looking at the states of affairs that would be produced by different partial plans, you look at underspecified plans and try to reason about ways to improve their utility. An underspecified plan for making a meal, for instance, might consist of the **unordered** set *prepare starter, prepare main course, prepare dessert*. Given such a skeleton, you might refine it by deciding on the order in which you want to carry out these actions, so you might decide that the starter should be prepared first, and then the main course, and then the dessert. Or you might refine it by choosing what main course to have, and then choosing starters and desserts that will complement this main course, and only then deciding on the order in which to prepare them.

Plan space search originates with work on planning by analogy (Carbonell, 1983) and on metaplanning (Stefik, 1981a, 1981b). As with state space search, you can search backward or forward or use some combination of both. Plan space search seems to be very effective for problems where the effects of an action can be checked by direct inspection, but if the consequences of some action can vary depending on the situation in which it is carried out, then state space search may be a better choice.

The STRIPS formalism can be employed in any domain where actions can be characterized in terms of preconditions and effects. Is it possible to give such characterizations of linguistic actions?

Suppose, for instance, you wanted to describe what is involved when you inform someone of some fact. Consider the following schema:

$$
\begin{aligned}
&\mathit{action}(\mathit{inform}(S, H, P),\\
&\quad \mathit{preconditions}([\mathit{believe}(S, P),\\
&\qquad\qquad \mathit{not}(\mathit{believe}(S, \mathit{know}(H, P)))])\\
&\quad \mathit{effects}([\mathit{believe}(H, P),\\
&\qquad \mathit{believe}(S, \mathit{believe}(H, P))])\\
&\quad \mathit{subActions}([\mathit{state}(P')])
\end{aligned}
$$

This says that for a speaker S to successfully inform a hearer H of some proposition P, the speaker must believe P, and the speaker must not believe that the hearer already knows P. After the action is successfully performed, then H will believe P and S will believe that H believes P. In order to carry out such an action, you have to utter some sentence P' that encodes the proposition P.

Much of this seems reasonable enough. In particular, it draws out some of the distinctions between informing somebody about something; simply saying it to them (which you can do at any point: you can say 'I used to own a green cat' at any moment, but you cannot inform anybody that you used to own a green cat unless you actually did, which is unlikely to be the case); and reminding or nagging them about it – if you say 'You haven't done the washing up' in a situation where it is clear that your hearer knows they haven't done it, you are nagging them, not informing them. Furthermore, the suggestion that after you have informed someone of P then they will believe it, and you will believe they believe it, also seem reasonable. So it looks as though linguistic actions can be described within this framework:

$$
\begin{aligned}
&\mathit{action}(\mathit{nag}(S, H, P),\\
&\quad \mathit{preconditions}([\mathit{believe}(S, P),\\
&\qquad\qquad \mathit{believe}(S, \mathit{know}(H, P))])\\
&\quad \mathit{effects}([\mathit{believe}(H, P),\\
&\qquad \mathit{believe}(S, \mathit{believe}(H, P))])\\
&\quad \mathit{subactions}([\mathit{state}(P')])
\end{aligned}
$$

$$
\begin{aligned}
&\mathit{action}(\mathit{query}(S, H, P),\\
&\quad \mathit{preconditions}([\neg(\mathit{believe}(S, P)),\\
&\qquad\qquad \neg(\mathit{believe}(S, \neg(P))),\\
&\qquad\qquad \mathit{believe}(S, \mathit{know}(H, P)\\
&\qquad\qquad\qquad \vee \mathit{know}(H, \neg(P)))])\\
&\quad \mathit{effects}([\mathit{believe}(H,\\
&\qquad\qquad \mathit{want}(S, \mathit{know}(S, P)\\
&\qquad\qquad\qquad \vee \mathit{know}(S, \neg P))))])\\
&\quad \mathit{subActions}([\mathit{question}(P')]))
\end{aligned}
$$

Knowledge, Belief, and Action

Suppose you had a set of action schemata of this kind and you wanted to use them for planning what to say, or for interpreting what has been said to you. Is it possible to use any of the standard planning algorithms?

Consider, for instance, a situation in which you want to express your annoyance that I have not done the washing up. You might decide that nagging me about it would relieve your feelings. In order to do this, you have to carry out the following actions:

1. You have to verify that the preconditions hold, i.e., that you believe I haven't done it and that you believe I know I haven't done it.
2. You have to find a form of words that says that I haven't done it.

It seems very unlikely that you could check the preconditions by inspection of some description of the world. For blocks world problems you can just look at the current configuration of the blocks and see whether something is clear. This just isn't going to work when the preconditions are concerned with beliefs, and nested beliefs, and negated beliefs. Verifying the preconditions of an action like *nag* requires to you to carry out inference about your own and your hearer's knowledge and belief.

This requirement is even more marked when we consider how you would choose which action to perform in the first place. Informally, nagging someone about doing the washing up involves some chain of reasoning like the following:

1. Steven hasn't done the washing up, even though it's his turn.
2. He'll do it if I make him feel guilty about it.
3. He'll feel guilty about it if he becomes aware that I know that he knows that he hasn't done it even though it's his turn.
4. So I'll say "You haven't done the washing-up" in an appropriately bad-tempered manner.

Note the complex nesting of who knows what at step 3. To make someone feel guilty you have to let them know them know that you are **mutually aware**, or something pretty close to it, of the relevant facts. Note also that you probably don't have to say 'You

haven't done the washing up, even though it's your turn.' You and your hearer would both know that there was a mutually agreed rota of domestic tasks, and you would expect him to add the fact that you are now mutually aware that he hasn't done the washing up to this shared knowledge to arrive at the conclusion that you want him to feel guilty.

There are a lot of loose ends in this informal discussion (particularly concerning the notion of mutual knowledge [Moore, 1984; Fagin and Halpern, 1989]), but it should be clear that once you start reasoning about the preconditions and effects of even quite simple speech acts you need to be able to carry out inference about nested knowledge and beliefs.

A great deal of AI work on reasoning about knowledge and belief has built on Hintikka's (1962) observation that if you write down a set of rules for this task, they tend to look like rules of some modal logic. Consider, for instance, the following fairly intuitive observations about knowledge and belief:

1. If you know something it must be true (note the difference between 'I used to believe that the earth was flat, but now I realize I was wrong' and 'I used to know that the earth was flat, but now I realize I was wrong.' As soon as you realize that you were wrong, you have to downgrade your previous opinion from knowledge to belief, because you can't know something that isn't true).
2. You can carry out reasoning with what you know and believe. If you believe that it is Steven's turn to do the washing up, and you believe that he has not done it, then you can add the proposition that he has broken the rules of our arrangement to your belief set.
3. You can reflect on what you know and believe. For me to be confident about writing an article about speech acts, for instance, I have to believe that I know something about the topic. Simply knowing about the topic will not suffice: I have to **believe** that I know about it. (Of course, my belief that I know about the topic may be ill founded, but that would not stop me. What matters is my belief that I know about it.) How did I come by this belief? By reflecting on what I know about it, and deciding that the sources from which I have gained my knowledge are reliable.

If you try to turn these into a set of axioms as the basis of a logic of knowledge and belief, you will end up with something like the following:

(i) $\forall X \forall P(know(X, P) \rightarrow \mathrm{P})$

(ii) $\forall X \forall P(know(X, P) \rightarrow bel(X, P))$

(iiia) $\forall X \forall P \forall Q((know(X, P) \,\&\, know(X, P \rightarrow Q)) \rightarrow know(X, Q))$

(iiib) $\forall X \forall P \forall Q((bel(X, P) \& bel(X, P \rightarrow Q)) \rightarrow bel(X, Q))$

(iva) $\forall X \forall P(know(X, P) \rightarrow know(X, know(X, P)))$

(ivb) $\forall X \forall P(bel(X, P) \rightarrow bel(X, bel(X, P)))$

(v) $\forall X \forall P(bel(X, bel(X, P)) \rightarrow bel(X, P))$

(i) and (ii) say that whatever you know must be true and that you will believe anything you know, (iiia) and (iiib) say that you can carry out inference over your knowledge and beliefs, (iva) and (ivb) say that you can introspect about what you know and believe, and (v) says that you trust your own beliefs (there is no need for a version of [v] dealing with knowledge, since this would follow directly from [i] anyway).

These axioms look very similar to the standard axioms of modal logic, so that it may be possible to reason with them using techniques that have been developed for modal logic. This is attractive in itself, since it means that there may be no need to devise new inference engines for dealing with knowledge and belief. It becomes even more appealing when you realize that the STRIPS notation for actions is itself a shorthand for a modal logic. Modal logic is concerned with notions of possibility and necessity, which are interpreted by introducing a notion of 'accessible possible worlds.' Roughly speaking, some proposition is possible if you could imagine being in a situation where it is true. Of course, exactly what you can imagine depends on who you are. This variation is captured by allowing different accessibility relations between possible worlds – if you are prepared to suspend the laws of physics, then you can imagine a world in which objects can travel faster than light; if you are prepared to suspend the details of the physical structure of the universe we live in but not the general laws of physics, you can imagine a world in which objects can travel faster than 300 000 km/s.

The notion of possible worlds doesn't **explain** what is meant by saying that something is possible, since there is a clear circularity here. But it does provide a framework for considering different notions of possibility, and it has been widely used when trying to develop inference mechanisms for reasoning about possibility (and necessity, since a proposition P is necessarily true exactly when its negation is not possible: $nec(P) \leftrightarrow \neg(poss(\neg(P))))$.

It is easy to see a connection between the STRIPS notation for actions and the idea of possible worlds. If you could perform an action A whose effects include the proposition P then P would be true in the

world that resulted from performing *A*. So if the set of possible worlds is taken to be the set of states of affairs that could be obtained by performing one of the available actions, the logic that is defined by the STRIPS operators is just standard modal logic. Actually, it's not quite that simple, because the standard STRIPS notation exploits a default assumption that propositions don't change their truth value unless some action explicitly changes it. This assumption has to be added to modal logic, and doing so makes things a bit more complex, but the basic ideas are fairly similar.

If reasoning about knowledge and belief and reasoning about actions can both be done by exploiting the same mechanisms, then it should be possible to combine the two very smoothly. Just define different notions of accessibility and use the same engine.

The idea that you could combine reasoning about actions and reasoning about beliefs in this way was explored in Moore (1984), and was further developed for reasoning about speech acts by Appelt (1985). If you can describe speech acts by using a STRIPS-like formalism which talks about knowledge and belief in the preconditions and effects lists, and you have a general framework for reasoning about actions, knowledge, and belief, then surely you have a way of reasoning about speech acts.

Problems

Just how good is this kind of formalism for describing speech acts? Is it possible to use this kind of approach for determining whether 'The door's open' is a simple statement of fact or an invitation to come in, or whether 'Could you pass me the salt?' is a straightforward inquiry about the hearer's capabilities or a request to be passed the salt?

It is clear that something of this kind underlies these indirect utterances. Utterances like these do lead to different consequences in different situations, and the reason why they do so is that their function is to satisfy epistemic preconditions of some action within a larger plan. Why would someone who wanted to know the time say 'Do you know the time?' What they really want to do is to ask 'What is the time?' but they know that their hearer won't be able to answer this question unless they have the required information. So before asking the question they really want answered, they make sure that their hearer is in a position to answer it. But if the hearer is capable of reasoning about why the speaker asked the preparatory question, and hence taking a shortcut whereby they answer both the preparatory question and the substantive one – 'Yes, it's nearly 11' – then they are also capable of reasoning about why the speaker wanted to ask the substantive question in the first place, and hence saying 'No, but it's OK, they haven't called last orders yet.' (In English pubs the bar staff make it pretty clear when closing time is approaching and you only have a few minutes left to order a drink.)

The need for such an approach is thus evident, with a substantial body of work attempting to provide computer systems that embody these ideas reported in Cohen *et al.* (1990). There remain, however, two open questions: (i) does characterizing a set of speech acts within some AI planning framework provide a useful link between the simple surface meaning and the speaker's goals, and (ii) if it does, are current AI planning algorithms good enough to make use of these distinctions?

The answer to the second of these questions is simple. No existing AI planner can carry out all the inference required for linking 'Do you know the time?' to 'It's OK, they haven't called last orders.' Plan space planners cannot even attempt to solve this kind of problem, since they rely on static analysis of the relations between preconditions and effects. Descriptions of speech acts are extremely underspecified, and determining the consequences of even a fully determined utterance in a given context can require arbitrary amounts of epistemic reasoning. As such they are not susceptible to this kind of static analysis. Backward-chaining state space planners, however, can be adapted for this problem. The key observation here is that you cannot generally verify the preconditions of a speech act by inspection. In many cases, you have to try to **prove** that the preconditions hold. If your inference engine is allowed to construct hypothetical proofs by taking the effects of actions as things that wouldbe true if the action were performed, you can integrate planning and reasoning in a fairly seamless way (Field and Ramsay, 2003, 2004).

Even so, if you combine the difficulty of carrying out epistemic reasoning over a nontrivial knowledge base at all with the extra complications that arise from ensuring that you have a coherent plan, then the task can become extremely challenging. To solve it using current planners, you need a library of known plan schemata to have any real hope of responding within an acceptable period of time.

If the planning activity is in general so complex, does introducing a set of fine-grained speech acts make it any easier? If there were surface markers to distinguish nagging from reminding, and reminding from informing, and informing from lying, then things would be much easier. If you said 'I am now nagging you about the washing up,' or 'I am now asking you whether you know the time in preparation for asking a supplementary question about what time it is, in order to know whether it's too late to buy

another drink,' then the planning and plan recognition tasks would be greatly simplified. But people don't talk like that, except in situations where it is crucial to avoid any potential for ambiguity (legal cases, military operations). In everyday situations we say 'You haven't done the washing up' and 'Do you know the time?' and rely on the hearer to infer what we actually want them to do.

If you knew that someone was asking a preparatory question, then you could try to reason about what they were planning to do next. If you knew someone was nagging you then you could try to think of an excuse. The trouble is that the surface form does not provide any very strong steer in the matter. 'You haven't done the washing up' and 'You haven't done anything wrong' don't carry very clear markers saying that the first is likely to be a nag and the second is likely to be a reassurance. To work out which is which, you have to carry out some fairly complex inference about who knows what, about likely obligations, and about likely goals. Once you have done this, you will be most of the way to understanding what the speaker really wants. The work you have to do in order to identify which speech act was performed is exactly the work that identifying the speech act helps you avoid doing.

A number of authors have therefore suggested being less ambitious about the range of speech acts that should be axiomatized. Bunt (2000), for instance, suggests restricting attention to the acts that have recognizable surface forms – asserting, questioning, commanding. When you look closely at these actions, however, you see that the preconditions and effects are rather bare. There are almost no constraints on the circumstances in which you can assert something; you can say 'I used to own a green cat' whenever you like. And because there are no constraints on when you can say it, there are also very few completely reliable effects. The only reliably predictable effect is that if I was actually listening, then we will share the knowledge that you said it, though neither of us need believe that it's actually true. It seems likely, then, that while the use of AI planning theory, particularly in conjunction with the use of libraries of common epistemic plans, will help us in building slightly more flexible dialogue systems, a number of foundational issues about why linguistic actions have any nontrivial effects remain unanswered.

Speech Acts and Grammar

Language as Action: Performatives vs Constatives

J. L. Austin (1962), in his posthumously published book *How to do things with words* was the first to introduce the idea of speech acts (SA), analyzing the relationships between utterances and performance. His first goal was to point out the limitations of truth conditional semantics, i.e., the (logical positivist) view of language that places truth conditions as central to language understanding. Austin was convinced that we do not just use language to **say** things (make statements), but also to **do** things (perform actions). He formalized this opposition in his so-called performative hypothesis (which he would later abandon) by contrasting two types of utterances: constative utterances, or constatives, and performative utterances, or performatives (*see* **Speech Acts**).

Constatives are essentially like the classical statements. Their function is to describe some event, process, or state of affairs. The proposition that is expressed can be either true or false. Some examples are given in (1). Note that actually, at the time of this writing, at least one of these utterances is false.

(1) a. I'm driving a green car.
b. I have four children.
c. I am expecting a baby.

By contrast, performatives are utterances that have no truth conditions (see below), but this does not mean that they are meaningless, as illustrated by the examples in (2) (from Truckenbrodt, 2004).

(2) a. I sentence you to 2 years in prison.
b. I name this ship 'Liberté.'
c. I accept your offer.
d. I promise to pick you up at the airport.
e. I warn you not to come to my house again.
f. I advise you to stop smoking.

Formally, the utterances in (1) and (2) are alike. They are all declarative sentences, in the first person singular, and use the present tense. They do not, however, do the same job. While the utterances in (1) are statements, the utterances in (2) are used to perform an action, i.e., to do something (promising, warning, advising, etc.), rather than to say that something is or is not the case. To be successful, the performative must be issued in a situation that is appropriate, in all respects, for the act in question: if the speaker does not meet the conditions required for its performance, then the utterance will be 'unhappy,' 'void,' or 'infelicitous' (Austin, 1975: 14).

The conditions of 'happiness' of performative utterances (later called felicity conditions, see below) state how and when utterances are valid, in a real situation. A performative can be unhappy in two ways:

- The circumstances and conditions in which the utterance is performed are not appropriate (incorrect uttering of the formula, the actors involved do not meet the conventional requirements, the speaker is joking, etc.), in which case the act in question is not successfully performed at all, i.e., it is not achieved; or
- The utterance is issued insincerely (such as when I say *I promise* and have no intention of keeping it), in which case the act **is** achieved but with abuse of the procedure (I have promised but will not follow my promise).

Summing up, performatives are different from constatives in at least two ways (see also Truckenbrodt, 2004). First, performatives are used to do something, they create new facts (other than the fact that someone has said that something is or is not the case). Thus, a judge saying (2a) under the right circumstances in court creates the fact that the hearer is sentenced to 2 years in prison. An authorized person saying (2b) in the right circumstances creates the fact that the ship now has a name. Likewise, by saying (2c) the speaker creates a fact of commitment to accept the offer. By promising, as in (2d), a promise has been made that has consequences. Similarly, in (2e), the listener has been warned; and in (2f), the listener has been given advice. These facts may seem to be relatively similar to the fact created by a statement (*viz.*, that someone has said that something is true). Nevertheless they are different. As Austin clearly indicated, for example, an explicit promise as in (2d) is not, and does not involve, the statement that one is promising. It is an act of a distinctive sort, the very sort named by this particular performative verb (*to promise*). Of course one can promise without doing so explicitly by using the performative verb *promise*, but if one does use it, one is, according to Austin, making explicit what one is doing but not stating that one is doing it.

The second way in which performatives are different from constatives is that performatives cannot be said to be true or false. If the utterances in (2) are performed under the appropriate circumstances, there is no issue of them being true or false. If they

are made under the right circumstances, and by the right person, they may be said to be automatically true, in a certain sense. But if they are not made under the appropriate circumstances, they do not become false; rather they become unhappy or void, as shown above. It is clear that this is different from a statement being false. Instead, the statement represents an attempt to perform an act of the relevant kind, but an attempt that does not work out.

What About Grammar?

Performatives normally involve a first person subject (typically *I*) and a performative verb, as in (2) above (where the performative verbs are *promise*, *name*, etc.). Working with examples of everyday language to show how performances can happen, Austin (1975: 151) claimed five general classes of performative verbs (even though he admits that the distinction between various kinds of utterances is not always clear):

1. Verdictives, which give a finding or verdict by a jury, arbitrator, or umpire (sentencing, pleading, pronouncing, etc.).
2. Exercitives, which are the exercising of a power, right, or influence (appointing, voting, ordering, urging, advising, warning, etc.).
3. Commissives, which commit you to an action, including declarations or announcements of intention (promising, announcing, opening, declaring, etc.).
4. Behabitives, expressing attitudes about social behavior (apologizing, congratulating, commending, condoling, cursing, challenging, etc.).
5. Expositives, which make plain how utterances fit into conversations or arguments (I reply, I argue, I concede, I illustrate, I assume, etc.).

Performatives moreover tend to use the simple present tense and are indicative (*I promise I'll come tomorrow*). This is because they are pronounced for the purpose of acting on a real situation, and thus they usually cannot refer to past events. Nevertheless, performatives are also regularly found in the passive voice, as in (3) (from Austin, 1975: 57).

(3) You are hereby authorized to pay.
Passengers are warned to cross the track by the bridge only.
Notice is hereby given that trespassers will be prosecuted.

Noteworthy about these examples is that they contain the adverbial *hereby*. The insertion of this adverb is indeed often suggested as a test meant to distinguish performatives from constatives. All utterances in (2) allow the presence of *hereby* (see [4]), while the constatives in (1) do not (see [5]).

(4) a. I *hereby* sentence you to two years in prison.
b. I *hereby* name this ship 'Liberté.'
c. I *hereby* accept your offer.
d. I *hereby* promise to pick you up at the airport.
e. I *hereby* warn you not to come to my house again.
f. I *hereby* advise you to stop smoking.

(5) a. # I'm *hereby* driving a green car.
b. # I *hereby* have four children.
c. # I am *hereby* expecting a baby.

This difference between constatives and performatives is found across languages. In French *par la présente* works like English *hereby*, the German counterpart is *hiermit*, the Dutch one is *bij deze(n)*, the Spanish one is *por la presente*, etc.

As mentioned above, it is not absolutely necessary to actually pronounce the performative verb *to promise* to perform the action of promising. In principle, utterance (6a) will probably have a similar effect on the hearer as does utterance (2d), repeated here as (6b) for convenience.

(6) a. I'll pick you up at the airport.
b. I promise to pick you up at the airport.

Thus, in some sense, all verbs can be performatives. To account for this, Austin refined his classification: the utterances called performatives above are now called explicit performatives. These are distinguished from primary performatives, in which the performative part is implicit, as in (6a). Austin eventually realized that explicit constatives function in essentially the same way as performatives. After all, a statement can be made by uttering *I assert* . . . or *I predict* . . ., just as a promise or a request can be made with *I promise* . . . or *I request* . . . In addition, the utterances in (7) illustrate that explicit constatives can cooccur with *hereby*, and that they are automatically true, which makes them totally identical to explicit performatives, whereas the corresponding primary performatives to (7) are statements, not actions (see [8]).

(7) a. I (hereby) tell you that I am not traveling to the U.S. next week.
b. I (hereby) assert that this president is the most stupid one we ever had.

(8) a. I am not traveling to the U.S. next week.
b. This president is the most stupid one we ever had.

As pointed out by Thomas (1995), Austin's performative hypothesis convincingly documented the fact that people do not use language just to make

statements about the world: they also use language to perform actions that affect the world in one way or another. However, the position that **only** performative verbs could be used to perform actions turned out to be untenable. Thomas (1995: 44–46) gives three different reasons for the collapse of Austin's performative hypothesis.

- There is no formal (grammatical) way of distinguishing performative verbs from other sorts of verbs. Like all other verbs, performatives can be plural as well as singular, they can be written and spoken, they do not have to be in the first person, nor is it essential that they be in the active mood.
- The presence of a performative verb does not guarantee that the specified action is performed. One can indeed use the verb *to promise* to actually perform a threat, rather than a promise, as in *I promise things will go wrong for you if you don't go to bed immediately!*
- There are ways of doing things with words that do not involve using performative verbs. Indeed, for a great many very common acts such as offering, boasting, expressing an opinion, hinting, insulting, etc., it would be most odd to use a performative verb. In addition, there are also acts for which the language does not even have a performative verb, such as letting the cat out of the bag, putting one's foot in it, pulling someone's leg, etc.

As a consequence, Austin completely abandoned his original distinction between constative and performative utterances; instead, he distinguished between the truth conditions of statement and those of the action it performs. In other words, the proper distinction is that between locutionary and illocutionary acts.

Locution, Illocution, Perlocution

In addition to providing the insight that utterances are used to perform actions, speech act theory assumes that speakers are simultaneously involved in three different speech acts when uttering a sentence:

1. a locutionary act: the act of using words to form sentences, those wordings making sense in a language with correct grammar and pronunciation.
2. an illocutionary act: the intended action by the speaker, the force or intention behind the words, within the framework of certain conventions.
3. a perlocutionary act: the effect that an utterance has on the thoughts, feelings, attitudes, or actions of the hearer.

These acts are not parts, but dimensions of a speech act, which means that they cannot be performed in isolation. Any utterance will always exhibit all of these different dimensions. Thus, in order to have a speech act one needs a meaningful linguistic expression (locution), that is produced, one, with some kind of function or communicative purpose in the speaker's mind, such as making a statement, an offer, an explanation, a threat, etc., (illocution), and two, with some intended effect on the hearer, such as to get the hearer to perform some action, or to have her/him understand a problem, etc., (perlocution). Bach (2003) illustrates this with the example given in (9):

(9) The bar will be closed in five minutes.

In uttering (9), a bartender would be performing the *locutionary* act of saying that the bar (i.e., the one he is tending) will be closed in 5 minutes (from the time of utterance). In saying this, the bartender is performing the illocutionary act of informing the patrons of the bar's imminent closing (and perhaps also, and not unimportantly, the act of urging them to order a last drink). Finally, the bartender also intends his utterance to produce further effects, by performing the perlocutionary acts of causing the patrons to believe that the bar is about to close and of actually getting (and not just urging) them to order one last drink. He is performing all these speech acts, at all three levels, just by uttering the above words.

Of these three dimensions, the one most discussed is the illocutionary act (also referred to as the illocutionary force). The term 'speech act' has indeed come to refer exclusively to this kind of act, which thus corresponds most closely to the notion of performative described above, as they can (but need not) be performed by means of a performative formula.

What About Grammar?

Generally speaking, there is a close and predictable connection between locution and illocution of an utterance. That is, all competent (adult) speakers of a language can mostly predict or interpret the intended illocutionary force of an utterance with reasonable accuracy. As pointed out by Thomas (1995: 50), "human beings simply could not operate if they had no idea at all how their interlocutor would react (...)." Most typically, the sentential moods declarative, interrogative, and imperative (*see* **Mood and Modality in Grammar**) are used with the functions shown in Table 1 (based on Truckenbrodt, 2004) .

However, this relation between form and function only works in the typical cases (and it remains questionable whether these cases are the most frequent ones). Clearly, we cannot say: a declarative has by

Table 1 Relationship between form and function of speech acts

Syntactic form	*Illocutionary act*	*Illocutionary force*
Declarative	Statement	Speaker commits to content
Interrogative	Question	Request for information
Imperative	Command	Attempt to get listener to do something

definition the function of a statement, or an interrogative has by definition the function of a question (see below). This means that sometimes things can go wrong, mostly because the same locutionary act can have different illocutionary forces. For instance, depending on the context of utterance, (10) – a declarative – could count as a prediction, a promise, or a warning.

(10) I'll be back.

The most obvious way to help the hearer recognize the intended illocutionary force of an utterance is by using an explicit illocutionary act. Explicit acts contain a so-called IFID or illocutionary force indicating device, i.e., an expression naming the act. In most cases, this is a performative verb that explicitly names the illocutionary act being performed (I *warn* you that, I *predict* that, I *promise* that, etc.). While speakers do not always make their speech acts this explicit, still the context may force them to identify the speech act being performed. This is illustrated in the (constructed) telephone conversation in (11) (from Yule, 1996: 49–50).

(11) Him: Can I talk to Mary?
Her: No, she's not here.
Him: I'm asking you – can I talk to her?
Her: And I'm telling you – SHE'S NOT HERE!

In this scenario, each speaker describes the illocutionary force of their utterances. Most of the time, however, no performative verbs are mentioned. Yule (1996) mentions some further IFIDs that can draw the attention to the illocutionary force being employed, such as word order, stress, intonation, changes in voice quality, etc.

Of course, to be recognized, the utterance should also be produced under certain (conventional) conditions for it to count as having the intended illocutionary force; that is, it should meet a number of felicity conditions, a notion that was developed by Searle (1969), building on Austin's original work. In addition to the general conditions on the participants (such as that they understand the language being used and that they are not play-acting or uttering nonsense), Searle distinguishes preparatory, propositional, sincerity, and essential conditions, differing as to the function of the speech act at hand. Example (12) illustrates the conditions for the act of *promising* (Searle, 1969: 62ff; as cited in Saeed, 2003: 229):

(12) Conditions for promising
[where S = Speaker, H = Hearer, A = the future action, P = the proposition expressed in the speech act, *e* = the linguistic expression]
a. Preparatory 1: H would prefer S's doing A to his not doing A and S believes H would prefer S's doing A to not doing A.
b. Preparatory 2: It is not obvious to both S and H that S will do A in the normal course of events.
c. Propositional: In expressing that P, S predicates a future act of S.
d. Sincerity: S intends to do A.
e. Essential: the utterance *e* counts as an undertaking to do A.

Thus, the preparatory conditions for a promise should guarantee that when I promise to do something, the event will have a beneficial effect on the hearer, and second, it will not happen by itself. So, telling one's spouse *I'll be home at six* when leaving for work might not be considered a typical promise, unless I usually come home at seven or eight and my spouse would like me to come home earlier. The propositional condition reflects the fact that the content of the utterance has to concern a future event – I cannot promise something that already has happened – and that the future event will be an act of the speaker – I cannot promise my family that our neighbor will do the dishes tonight. Related to these conditions is the sincerity condition: when I promise to do something, I really must intend to carry out the future action – I cannot genuinely promise that I will be home at six if I already know that I have a meeting starting at six! Finally, the essential condition covers the fact that by uttering my promise, I commit myself to the obligation of carrying out the future action.

According to Searle, the conditions related to the speech act of promising are of general applicability and thus it should be possible to establish rules of this type for every speech act. Searle does so for some eight additional speech acts: requesting, asserting, questioning, thanking, advising, warning, greeting, and congratulating. Thomas (1995: 95ff), however, criticizes Searle's endeavor and raises four interrelated sets of problems with respect to these rules:

- It is not always possible to distinguish fully between one speech act and another (partly because the conditions specified by Searle only tend to cover the central or most typical usage of a speech act verb).

- If we attempt to plug all the gaps in Searle's rules, we end up with a hopelessly complex collection of *ad hoc* conditions.
- The conditions specified by Searle may exclude perfectly normal instances of speech act, while they would permit anomalous uses.
- The same speech act verb may cover a range of slightly different phenomena and some speech acts do indeed overlap; Searle's rules do no account for this.

Categorizing Speech Acts

Any language has probably several hundred verbs that can be used to describe a kind of action that can be performed with an explicit or an implicit speech act. Is there a plausible way of grouping all these different speech acts into categories? In contrast to Austin's (1962: 109ff) first, very tentative classification, based on actual performative verbs (a classification which he did not consider definitive), Searle's (1976) categorization of speech acts into five types, each with their general function, has become a classic, and is still often referred to today. Its main improvement with respect to Austin's is probably that it clearly separates the notion of speech act from that of speech act verb. In other words, "the existence or nonexistence of [a speech act verb (or performative verb)] cannot be a criterion for the existence or nonexistence of a particular speech act" (Mey, 2001: 117) (*see* **Speech Acts: Definition and Classification**).

1. Representatives commit the speaker to something's being the case, to the truth of the expressed proposition, typically statements, assertions, conclusions, descriptions, etc., such as *The earth is flat; It's cold here; Chomsky didn't like butterflies*.
2. Directives are attempts by the speaker to get the hearer to do something. They express what the speaker wants; typical representatives are commands, orders, requests, suggestions, etc., such as *I warn you to stay away from my house!; Mum, can I have a cookie, two please?*
3. Commissives commit the speaker to some future course of action. They express what the speaker intends: typically, promises, threats, refusals, offerings, etc., such as *I promise that I'll be home at six; I'll be back; I will not marry you*.
4. Expressives are used to express the psychological state of the speaker. They state what the speaker feels and can be statements of joy, pain, sorrow etc., but also expressions of thanking, apologizing, welcoming, congratulating, etc., such as *I congratulate you on winning the race; I'm really sorry; YESSS!*
5. Declarations effect immediate changes in the institutional state of affairs, i.e., they change the world via the utterance. The speaker has to have a special institutional role, in a specific context, in order to be able to perform a declaration appropriately; typical examples include excommunicating, declaring war, marrying, firing from employment, nominating, etc.

Searle uses a mix of criteria to establish these different types; these include the act's illocutionary point, its fit with the world, the psychological state of the speaker, and the content of the act (cf. Saeed, 2001: 228–229; Mey, 2001: 119–126). The illocutionary point is the purpose or aim of the act; it corresponds most closely to the definition of the speech act types given above. The fit concerns the direction of the relationship between language and the world: should the words conform to the world (representatives, expressives) or is it the world that should conform to the words (directives, commissives), or be changed by the words (declaratives)? The psychological state relates to the speaker's state of mind or attitude toward events: e.g., does the speaker believe what is uttered in the speech act, or not? Finally, the content is directly related to the propositional felicity condition described above.

What About Grammar?

An alternative way of classifying speech acts is to take their structure as a point of departure. In their cross-linguistic analysis of speech acts, Sadock and Zwicky (1985: 160) note "that most languages are similar in presenting three basic sentence types with similar functions and often strikingly similar forms." These three basic sentence types are the declarative, the interrogative, and the imperative. Roughly, they can be described as follows: The declarative is used for making announcements or declarations, stating conclusions, making claims, telling stories, and so on. The interrogative is used to gain information; it asks for a verbal response from the addressee. The imperative is used for making requests, giving orders or advice, making suggestions, and the like; its use is meant to influence the course of (future) events. While there are many differences in detail between individual languages, there seems to be "an easily recognized relationship between the three structural forms (declarative, interrogative, imperative) and the three general communicative functions (statement, question, command/request)" (Yule, 1996: 54), as illustrated in (13):

(13) a. She eats an apple. declarative/statement
b. Does she eat an apple? interrogative/question
c. Give me her apple! imperative/command

Whenever there is such a direct relationship between the sentence type and its communicative function, we are faced with a direct speech act. Whenever the relationship between structure and function is indirect, we are dealing with an indirect speech act. Thus, an interrogative used to ask a question is a direct speech act (as in 13b), but an interrogative used to inquire about a capability (*could, can*) or willingness (*would*) in order to elicit information (14a) or to make a request (14b, 14c) represents an indirect speech act (*see* **Speech Acts, Literal and Nonliteral**).

(14) a. Could you tell me whether she's eating an apple?
b. Can you give me the salt, please?
c. Would you give me your suitcase, Madam?

The examples in (14) actually display "a typical pattern in English whereby asking a question about the hearer's assumed ability (*Can you?*, *Could you?*) or future likelihood with regard to doing something (*Will you?*, *Would you?*) normally counts as a request to actually do that something" (Yule, 1996: 56). The same goes for other languages (such as Dutch, French, German, Spanish, and so on) where similar patterns are displayed.

From a more general point of view, indirectness is a universal phenomenon (Thomas, 1995: 119). It can be used to make one's language more or less interesting; to increase the force of one's message, to reach competing goals; and to be more polite or to save one's face (see Thomas, 1995: 143–146) (*see* **Face**). Indirect speech acts, in particular, are generally associated with greater politeness than are direct speech acts. However, it is not possible to assess politeness out of context. The linguistic form, as well as the context of utterance, and the relationship between speaker and hearer, all play a role in rendering a speech act more or less polite (or impolite; see Thomas, 1995: 155–157) (*see also* **Politeness; Pragmatics: Overview; Pragmatic Acts**).

Speech Acts, Literal and Nonliteral

A Capone, Barcellona, Italy

There has been a long and fierce battle between the communication-oriented philosophers of language and the formal linguistics theoreticians regarding the priority of language as a means of expressing thought over a vision of language as an instrument of communication. The philosopher Dummett, in a conciliatory tone, has attempted to demonstrate that both positions – in their radical assumption that the other view is misguided – are wrong and that the two ideas about language are compatible. According to Dummett (2003), the idea that language is used to communicate presupposes the view that language is a way of expressing (or articulating) thoughts. The idea that language is merely an instrument of the expression of thought, in his view, collapses when we consider solipsistic uses of speech acts (a person's writing a reminder to himself and hanging it on a kitchen wall, or a person's trying to find an answer to his own question). Such solipsistic uses still presuppose a derived idea of communication.

In this article, we grant that language is primarily an instrument of thought (enabling the articulation of thought); however, we also think that language is an instrument of social action. An utterance U expressing the thought X performs an action A if, by the expression of X, a certain configuration of elements (roles, rights, duties) is changed from state S to state S' (A) (S' being a function of A) not as a result of the indirect consequences of the thought X but as a result of the socially recognized effects of vocalizing it, brought about by the recognition of the thought X and of the official position that the speaker of U has taken by publicly vocalizing such a thought. A speech act is not brought into effect unless a thought X expressed by an utterance associated with X is recognized as having been in the mind as well as in the mouth of a speaker. Suppose I have the ability to decipher Sally's intentions by reading her mind, and her thoughts contain a sentence S conventionally associated with a speech act A; nevertheless, the silent utterance (her thought) has no social effect, as its vocalization has not been heard in public.

Speech acts have their effects not only because certain persons have appropriate thoughts, but mainly because these thoughts have been publicly expressed by means of utterances, that are socially noticeable events, bound to have certain conventional social consequences. A speech act A is normally brought into effect by means of a device that indicates illocutionary force, essentially some linguistic means conventionally adopted to vocalize a certain thought that, once it is vocalized in public, becomes associated with an action A. There has been a long controversy as to whether moods are in some ways associated with certain illocutionary forces, resulting in the abandoning of the respectable and reasonable orthodoxy that declarative sentences, interrogative sentences, and imperatives are normally associated with certain actions, such as expressing thoughts, asking questions, and modifying other people's behavior (Levinson, 1983). Very luckily, a number of linguists, including Geis (1995) and Capone (2003), have returned to the orthodoxy. It would be unreasonable to suppose that distinctions of mood have no semantic counterparts, as that would require admitting the vacuity of certain fundamental linguistic distinctions. If there are linguistic distinctions, these must have semantic work to do, and it is reasonable to expect them to be related to illocutionary forces, at least of basic types (very generically specified). This article follows Geis in distinguishing between the *literal speech act* performed in virtue of uttering a sentence having a certain mood and the *full, context-dependent cognate speech act*. The full, context-dependent speech act, in this author's opinion, is still a function of the corresponding literal speech act, context playing a role in further determining the illocutionary force of the utterance. The role pragmatics plays in fully determining the content of a speech act in context is to add features of meaning to the underdetermined speech act; thus, it is always possible

Speech Acts, Literal and Nonliteral

A Capone, Barcellona, Italy

© 2006 Elsevier Ltd. All rights reserved.

There has been a long and fierce battle between the communication-oriented philosophers of language and the formal linguistics theoreticians regarding the priority of language as a means of expressing thought over a vision of language as an instrument of communication. The philosopher Dummett, in a conciliatory tone, has attempted to demonstrate that both positions – in their radical assumption that the other view is misguided – are wrong and that the two ideas about language are compatible. According to Dummett (2003), the idea that language is used to communicate presupposes the view that language is a way of expressing (or articulating) thoughts. The idea that language is merely an instrument of the expression of thought, in his view, collapses when we consider solipsistic uses of speech acts (a person's writing a reminder to himself and hanging it on a kitchen wall, or a person's trying to find an answer to his own question). Such solipsistic uses still presuppose a derived idea of communication.

In this article, we grant that language is primarily an instrument of thought (enabling the articulation of thought); however, we also think that language is an instrument of social action. An utterance U expressing the thought X performs an action A if, by the expression of X, a certain configuration of elements (roles, rights, duties) is changed from state S to state S' (A) (S' being a function of A) not as a result of the indirect consequences of the thought X but as a result of the socially recognized effects of vocalizing it, brought about by the recognition of the thought X and of the official position that the speaker of U has taken by publicly vocalizing such a thought. A speech act is not brought into effect unless a thought X expressed by an utterance associated with X is recognized as having been in the mind as well as in the mouth of a speaker. Suppose I have the ability to decipher Sally's intentions by reading her mind, and her thoughts contain a sentence S conventionally associated with a speech act A; nevertheless, the silent utterance (her thought) has no social effect, as its vocalization has not been heard in public.

Speech acts have their effects not only because certain persons have appropriate thoughts, but mainly because these thoughts have been publicly expressed by means of utterances, that are socially noticeable events, bound to have certain conventional social consequences. A speech act A is normally brought into effect by means of a device that indicates illocutionary force, essentially some linguistic means conventionally adopted to vocalize a certain thought that, once it is vocalized in public, becomes associated with an action A. There has been a long controversy as to whether moods are in some ways associated with certain illocutionary forces, resulting in the abandoning of the respectable and reasonable orthodoxy that declarative sentences, interrogative sentences, and imperatives are normally associated with certain actions, such as expressing thoughts, asking questions, and modifying other people's behavior (Levinson, 1983). Very luckily, a number of linguists, including Geis (1995) and Capone (2003), have returned to the orthodoxy. It would be unreasonable to suppose that distinctions of mood have no semantic counterparts, as that would require admitting the vacuity of certain fundamental linguistic distinctions. If there are linguistic distinctions, these must have semantic work to do, and it is reasonable to expect them to be related to illocutionary forces, at least of basic types (very generically specified). This article follows Geis in distinguishing between the *literal speech act* performed in virtue of uttering a sentence having a certain mood and the *full, context-dependent cognate speech act*. The full, context-dependent speech act, in this author's opinion, is still a function of the corresponding literal speech act, context playing a role in further determining the illocutionary force of the utterance. The role pragmatics plays in fully determining the content of a speech act in context is to add features of meaning to the underdetermined speech act; thus, it is always possible

to return from the contextualized speech act to the literal speech act by subtracting the features added by the context. Contextual transformations, in this author's view, are **conservative**, and the basic meaning structure can be identified both at the beginning and at the end of the transformation.

The full import of a speech act is determined by the interaction between the literal speech act and the context of use. As Mey says:

> Speech acts, in order to be effective, have to be situated. That is to say, they both rely on, and actively create, the situation in which they are realized. Thus, a situated speech act comes close to what has been called a speech event in ethnographic and anthropological studies (Bauman and Sherzer, 1974): speech as centered on an institutionalized social activity of a certain kind, such as teaching, visiting a doctor's office, participating in a tea-ceremony, and so on. In all such activities, speech is, in a way, prescribed: only certain utterances can be expected and will thus be acceptable; conversely, the participants in the situation, by their acceptance of their own and others' utterances, establish and reaffirm the social situation in which the utterances are uttered and in which they find themselves as utterers (Mey, 2001: 219).

I will call fully contextualized speech acts 'pragmemes,' on the basis of terminology by Mey (2002). A pragmeme is a speech act – an utterance associated with a goal (and an intention to bring about such and such effects), which is to modify a situation and change the roles of the participants within that situation or to keep the roles the same while bringing about other types of effects, such as exchanging or assessing information, or engaging in an interactional episode whose significance lies in the production of social gratification or, otherwise, social bonds.

Such a speech act is *situated*, which means that the specific form the utterance takes, interacts with features of the cotext and with the situation of utterance (*see* **Context, Communicative**), including the rules entailed by such a situation, that jointly determine (or contribute to determining) the global significance of the act in question. Given a sequence of utterances – literally interpretable as having a certain meaning and a certain goal – features of the situation of utterance, in the form of pragmatic reasonings based on the Gricean maxims (*see* **Maxims and Flouting**), will complete or expand the minimal proposition presented by the utterance, anchoring it to the discourse in question; other features of the context of utterance, in the form of defeasible or otherwise noncancellable aspects of meaning, will transform the literal signification of the utterance into a situational signification, removing ambiguities and imposing the stamp of the situation on the utterance, making certain rules of interpretation relevant to it and constituting a set of constraints that strictly enforce certain readings by discarding or eliminating other, irrelevant interpretation options.

A pragmeme is a situated speech act (Mey, 2001: 94) in which both the rules of the language and the rules of society intervene in determining meaning, intended as a socially recognized object sensitive to social expectations about the situation in which the utterance to be interpreted is embedded. A pragmeme always requires three types of embedding: the embedding of an utterance in a context of use, with an aim to determine the referential anchors that complete the signification of the utterance; the embedding in rules that systematically transform whatever gets said in a context into whatever is meant there; the embedding in the cotext, whose features are transferred onto the utterance by eliminating semantic or otherwise interpretable ambiguities and enriching further its (range of) interpretations, by making them more specific.

This article now discusses another example of language use in which the macro aspects of the situation contribute to transforming the illocutionary potential of an utterance. Capone (2005) discusses the utterance 'I saw you' in the context of a story by the Italian novelist Italo Calvino. Within the theoretical apparatus of Gricean pragmatics, the author argues that the standard illocutionary force of the utterance (both in the Italian and in the English version) is that of an accusation. There are, however, special contexts in which the utterance acquires particular illocutionary forces.

Let's look at the game played by children, usually under 10 years old, called hide-and-seek. In this game, one of the children has to count up to (say) 20, facing a wall or a tree and with his or her eyes shut. Upon finishing the count, he or she must then look for the other children. When he or she spots one of them, he or she has to call out 'I saw you' and then runs back to the place where the game started (wall or tree). The child who arrives there first wins. Now, what is the import of 'I saw you' in this situation? Do we proceed from literal meaning until we arrive at the socially situated meaning? Do the literal meaning and the socially situated meaning diverge? It is not altogether clear to me that we are faced here with a crucial divergence. But what is the socially situated meaning of 'I saw you'? We can assume that in the situation of the game, from an informational point of view 'I saw you' is totally purposeless, as visual contact ensures in the standard case that it is obvious to both the speaker and the addressee that the latter has been spotted (of course, there may be situations in which a physical obstacle prevents this mutual vision). In the game, however, the purpose associated with the utterance

is to start a sequence in which the children start running at the same time to the place where the game started. In its performative aspects, the utterance roughly amounts to 'Let's start running.' The socially embedded meaning is not at odds with the literal meaning – after all, the assertion 'I saw you' provides the reason that the running sequence is initiated.

Another situation in which it is possible to observe utterances such as 'I saw you' is the classroom. The teacher notices that Michelangelo (his favorite student) whispers the answer to a question to his desk mate. The teacher says 'I saw you.' This is not just an utterance of blaming but an order to Michelangelo to stop doing what he has been doing. How can this speech act be transformed into the pragmeme 'Stop prompting'? It is the social situation, the rules and expectations about students' obligations and teachers' tasks, that promote the *inhibitive interpretation* of 'I saw you.' In this context, it is out of the question that the utterance could count as a compliment – such an interpretation simply cannot occur. In fact, even though the teacher thinks highly of Michelangelo and also admires him for helping his fellow students and even though Michelangelo knows that the teacher has this positive opinion about him, it is unlikely that he will choose a tortuous path of individual interpretation and proceed from considerations about his teacher's high esteem for him to the interpretation that the speech act counts as a compliment. Michelangelo will almost certainly prefer to follow the social path of interpretation rather than construct his own individual path. Thus, he is able to work out that in fact the teacher, despite his high opinion of him, wants Michelangelo to stop prompting answers to his desk mate. This example nicely instantiates the view that the context is the total social setting in which the speech event takes place, the meaning of an utterance being determined by its place in an interactional sequence. It also provides support for Mey's view that users and their language are at the core of all things pragmatic, the world of users being the very condition for doing pragmatics (Mey, 2001: 29).

To speak a language is to express thoughts in the form of linguistic utterances that employ words and follow combinatorial rules. When a person A speaks communicatively, she transmits a thought to a hearer H with a certain **official aim** and possibly with other consequential effects. By an utterance, a speaker can inform the hearer of a certain situation, express an inner state of mind (emotions or feelings), or modify the behavior of the recipient. In all cases, a certain thought is expressed by the vocalization of an utterance. A speech act, though, is not merely the expression of a thought. It is the vocalization of a certain representation of the world (external or internal) aimed at making official the display of an intention to change a state of things and at changing things by the public display of that intention. A speech act is a **public utterance**; it cannot be a silent thought, and its effects are obtained in virtue of its being a public thought. I hope that this suffices to settle the question of whether the communicative or the representational view of language should have priority. My stance is that we have to start with the basic function of

is to start a sequence in which the children start running at the same time to the place where the game started. In its performative aspects, the utterance roughly amounts to 'Let's start running.' The socially embedded meaning is not at odds with the literal meaning – after all, the assertion 'I saw you' provides the reason that the running sequence is initiated.

Another situation in which it is possible to observe utterances such as 'I saw you' is the classroom. The teacher notices that Michelangelo (his favorite student) whispers the answer to a question to his desk mate. The teacher says 'I saw you.' This is not just an utterance of blaming but an order to Michelangelo to stop doing what he has been doing. How can this speech act be transformed into the pragmeme 'Stop prompting'? It is the social situation, the rules and expectations about students' obligations and teachers' tasks, that promote the *inhibitive interpretation* of 'I saw you.' In this context, it is out of the question that the utterance could count as a compliment – such an interpretation simply cannot occur. In fact, even though the teacher thinks highly of Michelangelo and also admires him for helping his fellow students and even though Michelangelo knows that the teacher has this positive opinion about him, it is unlikely that he will choose a tortuous path of individual interpretation and proceed from considerations about his teacher's high esteem for him to the interpretation that the speech act counts as a compliment. Michelangelo will almost certainly prefer to follow the social path of interpretation rather than construct his own individual path. Thus, he is able to work out that in fact the teacher, despite his high opinion of him, wants Michelangelo to stop prompting answers to his desk mate. This example nicely instantiates the view that the context is the total social setting in which the speech event takes place, the meaning of an utterance being determined by its place in an interactional sequence. It also provides support for Mey's view that users and their language are at the core of all things pragmatic, the world of users being the very condition for doing pragmatics (Mey, 2001: 29).

Speech Acts: Classification and Definition

A Capone, Barcelona, Italy

To speak a language is to express thoughts in the form of linguistic utterances that employ words and follow combinatorial rules. When a person A speaks communicatively, she transmits a thought to a hearer H with a certain **official aim** and possibly with other consequential effects. By an utterance, a speaker can inform the hearer of a certain situation, express an inner state of mind (emotions or feelings), or modify the behavior of the recipient. In all cases, a certain thought is expressed by the vocalization of an utterance. A speech act, though, is not merely the expression of a thought. It is the vocalization of a certain representation of the world (external or internal) aimed at making official the display of an intention to change a state of things and at changing things by the public display of that intention. A speech act is a **public utterance**; it cannot be a silent thought, and its effects are obtained in virtue of its being a public thought. I hope that this suffices to settle the question of whether the communicative or the representational view of language should have priority. My stance is that we have to start with the basic function of

language, which is that of expressing or articulating thoughts, before we can move on to the public function of language, which is to express communicative intentions to obtain a number of effects on other people and on society. Thus, this view reconciles opposite stances to language.

We have to distinguish 'locutionary,' 'illocutionary,' and 'perlocutionary' acts. A locutionary act is the vocalization of a sentence endowed with a certain meaning. For example, an actor on the stage vocalizes a locutionary act, because the meaning that the utterance has, is not interpreted as being a display of the speaker's intention. An illocutionary act is an utterance proffered with the intention to change the context, updating it with a certain public intention to do things or modify the hearer's cognitive state. A perlocutionary act is an utterance that achieves the speaker's intention, not directly through the expression of that intention, but **as a consequence** of the display of a speaker's intention to do something. For example, an anonymous letter to the police may have as its point the (perlocutionary) intention to jam the police activities and divert the course of justice.

In this article, I contend that there is a general algorithm mapping a sentence type to a literal speech act; in other words, there are conventions of language use associating certain forms with certain speech acts. This is certainly the case of 'performatives' (e.g., *I promise to come tomorrow*; *You are fired*; etc.), forms which **unambiguously** express a certain illocutionary intention and the utterance of which counts as carrying out certain social actions. When a performative formula is used by a person having certain socially recognized characteristics (status, power, etc.) in an appropriate context, then a certain social action is carried out in virtue of the speaker having proffered the formula in that context. The case of utterances that do not wear their illocutionary potential on their sleeves is less certain, in that the context can shape the final illocutionary force of the utterance. However, it is useful, in my opinion, to think of the language system as providing default conventions whereby proffering a certain utterance, in virtue of a convention of use, counts as performing a certain speech act, unless the context intervenes to enrich the force of the utterance further. The basic objections to this view (counterexamples to basic correlations) can be answered by having some weak conventions of language use map utterances to very generic illocutionary forces that can be enriched further by the specification of the full context in which the utterance is situated.

It is useful here to abandon the view that there are sentences whose illocutionary potentials can be studied in isolation, and to replace it with one in which, although the very basic contribution of linguistic semantics is not dismissed altogether, one specifically studies speech acts in actual interaction, embedding them in large portions of context having the function of incrementing the illocutionary potential of a certain sentence. We will thus move on to a higher unit of linguistic analysis: the 'pragmeme.' We may provisionally define the pragmeme in this way:

> Take an utterance U of a sentence S in a cotext S′, S″, S‴, Sn, or a sequence Sq of utterances, uttered in a situation of utterance C, in which the language users know that the sequential placement of U or Sq contributes to the illocutionary force in virtue of a rule of language use pertaining to that limited area of use. Then the utterance of U or Sq in the cotext S′, S″, S‴, Sn and in the situation C will transform U or Sq into a pragmeme Pr having a certain illocutionary force IF partially determined by the semantic import of the sentence in question, by referential pragmatic enrichments and explicatures, and by the final transformation due to the contextual and cotextual elements of the sequence S′, S″, S‴, Sn, in C.

As can be noted, in the definition above we have avoided the ordinary assumption that there is a one-to-one mapping between an utterance (consisting of a single sentence) and an illocutionary act, preferring the general case in which a sequence of sentences (or utterances) counts as the vocalization of a single speech act (*see* **Pragmatic Acts**).

Before moving on to the important issue of speech act classification, it is important to try to settle the perennial question of whether speech acts can or cannot be reduced to truth-conditional meaning. In fact, speech act theory, as worked out by Austin (1962), seems *prima facie* to challenge the view that semantics can be reduced to truth-conditional meaning, because at least a number of speech acts (e.g., promises, directives, requests, etc.) do not represent thoughts or facts, but are instructions to change the world in a manner specified by the speech act at hand. In fact, Gazdar (1979) and Levinson (1983) persuasively write that speech acts are best described as transformations from a certain context to a new one (*see* **Austin, John Langshaw (1911–1960)**; **Speech Acts**). Of course, there are advantages to glean from this perspective, but it has not been demonstrated, according to a number of authoritative scholars, that a speech act does not express a thought, the intention on the part of the speaker to carry out a certain action. Surely, a person who asks a question expresses the wish to know a certain answer; a person who proffers a directive vocalizes the wish that the world be changed in such-and-such a way; a person who utters a promise expresses the thought that he or she will act in a certain manner in the future that will

create some advantages for the hearer. I believe that all this is indisputable, and I am not sure how it can be reconciled with the drastic view proposed by Austin and then followed by Levinson (1983) that speech acts cannot be reduced to truth-conditional meaning. After all, having a thought amounts to creating a state of affairs (albeit enveloped in the mind) that surely can be expressed by truth-conditional semantics, as this is specifically intended to describe states of affairs, either in the world or in the mind (and states of affairs in the mind are in the world, as a consequence of the fact that the mind is in the world).

One way to reduce speech acts to truth-conditional meaning is through partitions (Higginbotham, 1995). Consider a question such as 'Is John at home?' Because the question just admits two possible replies (Yes, he is; No, he is not), the speech act is associated with the partition [He is at home/he is not at home], which expresses the basic truth-conditional import of the question. A crucial observation to make, following Schiffer (2003), is that while we can happily say that the question is associated with this partition, it is not clear (and it is possibly wrong to think) that we are entitled to say that the question means what the partition means. At least, this is not the way we would ordinarily speak. More complicated are questions such as 'Which boy did you see in town?' where the partition consists of all the reply options related to the domain of the boys present in town (for all those boys, we have to consider the reply option [I saw x/ I did not see x]).

I tentatively propose another way to solve the problem of speech acts' reduction to truth-conditional meaning, by recourse to modal notions. Consider the following sentence:

> Go and buy some bread.

This sentence can be represented in the following way:

> In a world *w* that is maximally similar to the actual-world, such that the obligations imposed by the speaker on the hearer in virtue of linguistic conventions and of social conventions (for example, the institutional role played by the speaker or the kind of obligations under which the hearer has put himself are fulfilled, the hearer (or the recipient of the speech act in question) buys some bread.

Of course, this is no more than a sketch of a possible solution, but I am persuaded that it goes some way toward remedying the dichotomy between assertions and nonassertive speech acts, while allowing us to retain a more commonplace notion of meaning than that advocated by Higginbotham and his followers, using the plain and salutary intuitions by Schiffer.

It is now time to move on to a basic classification of speech acts. Let us start with 'assertions.' A speaker S asserts P: (a) if he or she believes he or she knows that P is true (or he or she feels justified in believing that P is true), and (b) if he or she further believes that the proffering of the assertion will effect a substantial change in hearer H's information state. The presupposition of an assertion P (which is not to be treated as a 'reminder') is that (a) the hearer does not know P, and (b) either he or she is interested in knowing P, or even in the case when he or she would prefer not to know P, the speaker has a moral duty to inform H of P. Part of the dynamics of asserting P is that the speaker believes that H can use the information contained in P to make plans for successful action. Although the assertion P amounts to an implicit claim on the part of the speaker that he or she knows that P is true, it is not necessary for the speaker to actually know that P is actually true in order to make such an assertion. What is indispensable is that the speaker has (subjective) reasons to believe that he or she has good grounds for asserting P. Neither is it necessary that the speaker should stick to his or her asserted proposition after it has been demonstrated through an evidential procedure that it is wrong. He or she can change his or her mind about P and retract the assertion, although by doing so he or she must give reasons for entertaining a different thought. 'Expressives' are to be treated separately from assertions because they are disclosures of the reality of the mind and of the heart, and are not verifiable except by reference to the consonance of a speaker's behavior with such disclosures. 'Directives' express the speaker's wish that the hearer do such-and-such a thing and are uttered with the presumption that the hearer is under some obligation to carry out the action in question (status and roles within an office or an institution determine the right to utter the directive in question). 'Requests' also express the speaker's wish that the hearer behave in such-and-such a way. Requests are not licensed by the formal rights acquired by being part of an institution, but by the obligations contracted by the hearer throughout previous interaction. 'Promises' are revelations of future behavior on the part of the speaker from which the hearer will glean some advantages. Promises concern actions that have been presumably solicited by the hearer (or by someone close to the hearer) (*see* **Speech Acts and Grammar**).

Speech Aerodynamics

J J Ohala, University of California, Berkeley, CA, USA

© 2006 Elsevier Ltd. All rights reserved.

From a mechanical point of view speech may be regarded as the conversion of slow air pressure variations into the rapid air pressure variations called 'sound.' Sound is created when the air under pressure is released; releasing it at regular intervals creates the periodic pulsation known as voicing; releasing it suddenly creates the transient impulses of stop bursts; releasing it in a sustained way over a span of a few tens of milliseconds creates the turbulence of affricates and fricatives; completely stopping the release creates the attenuation of sound found in stops. The creation and the management of these slow pressure variations and the generation of the air flow that produce the audible turbulence and impulsations are studied in speech aerodynamics. This article will review some of the basic aerodynamic principles applicable to speech and present some phonological data that are consequences of them.

As an aerodynamic mechanism, the vocal tract consists of a set of chambers connected by valves to each other and ultimately to the air space outside. Some of these chambers come with piston-like structures that can effect a change in their volumes (see **Figure 1**). The volume of the pulmonic cavity can be changed by the movements of the chest wall and the diaphragm. Virtually all human speech is superimposed on the expiratory phase of respiration when the chest wall contracts to elevate the air pressure in the lungs. In the production of ejectives and implosives, the larynx (and to some extent the pharyngeal walls) change the volume. During clicks (velaric ingressives) downward movements of the body of the tongue act to change the volume of the air trapped between the tongue and the palate (*see* **Phonetics, Articulatory**).

Certain phonetic and phonological universals are derived simply from the way these chambers are connected and the operation of their valves. For example, given that, of the two openings to the nasal cavity, only the velic valve is capable of complete closure – the nostrils remain permanently open – the obstruent character of any sound made that connects to the nasal cavity will be inhibited. Clicks are made with a mechanism that is independent of the other cavities and so can be made with simultaneous voicing, nasalization, etc.

Aerodynamic Principles

Pressure and Volume

In the following discussion, the unit of air pressure, 'cm H_2O' refers to the height of a column of water displaced by pressure impinging on the water. It is the most common unit used in phonetics for this purpose. This unit is similar to the unit of mm Hg (mercury)

Figure 1 Schematic representation of the speech mechanism as a system of chambers connected by valves. Some of the chambers have piston-like structures that can alter their volume.

From a mechanical point of view speech may be regarded as the conversion of slow air pressure variations into the rapid air pressure variations called 'sound.' Sound is created when the air under pressure is released; releasing it at regular intervals creates the periodic pulsation known as voicing; releasing it suddenly creates the transient impulses of stop bursts; releasing it in a sustained way over a span of a few tens of milliseconds creates the turbulence of affricates and fricatives; completely stopping the release creates the attenuation of sound found in stops. The creation and the management of these slow pressure variations and the generation of the air flow that produce the audible turbulence and impulsations are studied in speech aerodynamics. This article will review some of the basic aerodynamic principles applicable to speech and present some phonological data that are consequences of them.

As an aerodynamic mechanism, the vocal tract consists of a set of chambers connected by valves to each other and ultimately to the air space outside. Some of these chambers come with piston-like structures that can effect a change in their volumes (see Figure 1). The volume of the pulmonic cavity can be changed by the movements of the chest wall and the diaphragm. Virtually all human speech is superimposed on the expiratory phase of respiration when the chest wall contracts to elevate the air pressure in the lungs. In the production of ejectives and implosives, the larynx (and to some extent the pharyngeal walls) change the volume. During clicks (velaric ingressives) downward movements of the body of the tongue act to change the volume of the air trapped between the tongue and the palate (*see* **Phonetics, Articulatory**).

Certain phonetic and phonological universals are derived simply from the way these chambers are connected and the operation of their valves. For example, given that, of the two openings to the nasal cavity, only the velic valve is capable of complete closure – the nostrils remain permanently open – the obstruent character of any sound made that connects to the nasal cavity will be inhibited. Clicks are made with a mechanism that is independent of the other cavities and so can be made with simultaneous voicing, nasalization, etc.

Aerodynamic Principles

Pressure and Volume

In the following discussion, the unit of air pressure, 'cm H_2O' refers to the height of a column of water displaced by pressure impinging on the water. It is the most common unit used in phonetics for this purpose. This unit is similar to the unit of mm Hg (mercury)

Figure 1 Schematic representation of the speech mechanism as a system of chambers connected by valves. Some of the chambers have piston-like structures that can alter their volume.

used in meteorology and can be directly translated into it: 1 cm $H_2O = 0.736$ mm Hg. What the height of a column of mercury in a barometer reflects is the pressure of all the air above us, the atmosphere, which presses down on the surface of the earth. Thus it must be kept in mind that, in reality, even when the vocal tract is completely open, as for a vowel, there is air in the vocal tract and it is under pressure, 'atmospheric pressure,' and equal to about 1030 cm H_2O. Usually, for convenience, the pressure in the vocal tract is expressed relative to atmospheric pressure, that is, 10 cm H_2O lung pressure + 1030 atmospheric pressure = 1040 cm H_2O absolute.

The pressure of a given mass of air varies inversely with the volume it occupies. (This is the well-known Boyle-Mariotte's Law, but here temperature is neglected, assuming adiabatic conditions, that is, where pressure changes take place without any change in temperature.) This relation may be expressed mathematically as in (1), where P_1 and V_1 are the initial pressure and volume, respectively; P_2 and V_2, the same parameters later:

(1) $P_1V_1 = P_2V_2$
$P_2 = P_1 \times (V_1/V_2)$

Thus, for example, if during the production of an ejective stop the starting oral pressure and volume are 1030 cm H_2O and 100 cm^3, respectively, and the oral volume is reduced by 2 cm^3 (by raising the larynx or constricting the pharyngeal walls) to 98 cm^3, the pressure that will result will be:

(2) $P_2 = 1{,}030 \times (100/98)$
$P_2 = 1{,}051$ cm H_2O

Thus, this oral pressure, expressed relative to atmospheric pressure, will be $1051 - 1030 = 21$ cm H_2O. In fact, oral pressures during ejectives have been recorded in the range 10–21 cm H_2O and so we can conclude that they involve reductions in oral cavity volume of the order of 1–2 cm^3.

Pressure and Mass of Air

For a given volume, pressure increases directly with the mass of the air. This relation may be expressed mathematically as in (3), where M stands for the mass of the air (expressed in appropriate units):

(3) $P_1/M_1 = P_2/M_2$
$P_2 = P_1 \times (M_2/M_1)$

Air Flow

The volume of air that will flow from one cavity to another, depends on the size (principally the cross-dimensional area) of the channel between them and the difference in the pressures in the two cavities, as characterized in (4), where U is the volume velocity (expressed in cm^3/sec), A is the cross-dimensional area of the channel the air flows through and P_1, P_2 are the pressures on either side of the channel; c is a constant:

(4) $U = A \times (P_1 - P_2)^a \times c$
$U = A \times \Delta P^a \times c$

The exponent, a, varies between 0.5 and 1, depending on the nature of the flow; it is 1 when the flow is smooth (technically, 'laminar') and 0.5 when flow is turbulent. In the conditions found in speech production, that is, what is called 'nozzle flow,' this number may vary continuously between these two extremes. Naturally, the direction of air flow will always be from the cavity with greater pressure to that with lesser pressure, that is, when U is positive the flow is from the region with pressure P_1.

Particle Velocity

The velocity of air, v, (called 'particle velocity') is equal to the volume of air flowing per unit time in a given direction divided by the cross dimension of the channel, as given in (5):

(5) $v = U/A$

Thus if 100 cm^3 of air flows through the channel formed between the tongue and the palate during an /s/, with cross-dimensional area of 0.1 cm^2, the velocity will be:

(6) $v = (100\ cm^3/sec)/(0.1\ cm^2)$
$v = 1{,}000$ cm/sec

Particle velocity is important because it is related to the degree of turbulence in the airflow and hence the intensity of frication noise.

Intensity of Turbulence

Many treatments of speech aerodynamics introduce the concept of the Reynold's number to explain when airflow becomes turbulent and noisy. The Reynold's number for a given condition of airflow is a dimensionless number that is the product of several factors: the diameter of channel the air passes through, the viscosity and density of the air, and, most notably, particle velocity, v. Under ideal laboratory conditions, when the Reynold's number exceeds a certain threshold the airflow changes abruptly from smooth or 'laminar' to turbulent. However, in irregularly-shaped channels like the vocal tract and with air flow that usually has a turbulent entry into the vocal tract (when passing through the glottis), there is some degree of turbulence at almost any velocity. Under such conditions the relationship between particle

velocity and the degree of turbulence and hence frication noise is highly complex and nonlinear. Suffice it to say that, other things being equal, as the velocity of the airflow increases, the resulting noise level from the turbulence increases monotonically. Other factors which enhance the intensity of frication noise from turbulence are as follows:

1. The presence of an obstacle, technically a 'spoiler,' in the path of the moving air. The upper incisors constitute a highly effective spoiler and, thus, account for the intense noise associated with sibilant fricatives (i.e., those made at the dental, alveolar, retroflex, or palato-alveolar places of articulation).
2. The presence of a resonating cavity downstream of the turbulence. Thus, the most forward-articulated fricatives like [ɸ f θ] have much less intensity than those articulated further back such as [ç x χ].

Vibratory Action and the Bernoulli Effect

The Bernoulli effect is easily demonstrated: in each hand hold two long strips of flexible paper (e.g., newspaper) such that in hanging down they face each other and are about 3 to 5 cm apart. Then blow down between the strips of paper. They will come together and commence to vibrate. Vocal cord vibration (voicing) – and possibly the vibration of parts of the tongue during trills – is initiated in a similar way. The Bernoulli effect accounts for the force which sucks the vocal cords together when air flows through them. Bernoulli's Law is usually given as (7) where ρ is the density of the air, P is the pressure normal to the direction of airflow, and U, as before, is the volume velocity of the airflow:

$$(7)\quad P + \frac{1}{2\rho}U^2 = \text{constant}$$

When U increases, P decreases, possibly to the point where it is negative with respect to ambient pressure, and thus, the sides of the channel (the vocal cords) through which the airflows can be sucked together. Then the pressure behind the constrictions blows the vocal cords apart again, and the cycle of closing-opening commences. However, after vibration is initiated, the closing of the vocal cords is due in part to the elastic recoil of the tissue, not exclusively to the sucking action of the Bernoulli effect. To the extent that elastic restoring forces operate in vocal cord vibration, the mechanism constitutes a 'relaxation oscillator' and works on principles similar to those causing the regular rocking of the weight on the escape vent of certain designs of pressure cookers. Glottal pulsation occurring when the rest state has the vocal cords pressed together, for example, creaky voice, derives from the vocal cords operating primarily as a relaxation oscillator; the Bernoulli effect plays little part.

Some Phonological Consequences

Voicing and Devoicing

Voicing and Stops Voicing (vibration of the vocal folds) requires (a) an appropriate configuration of the vocal cords, that is, that they be adducted and have an appropriate tension and (b) that there be sufficient airflow through the glottis and pressure drop across the glottis. Anything which reduces the airflow would therefore tend to inhibit voicing. This is the case with obstruents which block the free flow of air and which have often been noted as disfavoring voicing. Many languages have only voiceless obstruents; few have only voiced ones.

Some elementary calculations can give a better 'feel' for this phenomenon. Assuming an initial oral cavity air mass of 100 mass units, *m.u.* (1 m.u./cm^3), oral air pressure, P_o, equal to atmospheric = 1030 cm H_2O, subglottal pressure $P_s = 1040$ cm H_2O, we can calculate how much air, ΔM would have to be added to the oral cavity in order to raise the oral pressure to the level of subglottal pressure, such that the pressure drop across the glottis would be $P_s - P_o = 0$. The procedure is as follows (where P_1 = initial P_o and P_2 = resulting P_o):

$$(8)\quad \begin{aligned} &(M_1 + \Delta M)/100 = P_2/P_1 \\ &(100 + \Delta M)/100 = 1040/1030 \\ &\Delta M = ((1040/1030) \times 100) - 100 \\ &\Delta M = 1 \text{ m.u.} \end{aligned}$$

Thus adding only 1 m.u., approximately 1 cm^3 of air, would raise oral pressure to a level typically encountered for subglottal pressure. Next, we may ask how long it would take for this pressure level to be reached. Typical values for glottal airflow during speech are 100 to 150 cm^3/sec. Taking the value of 100 cm/sec, we see that 1 cm^3 would be added in:

$$(9)\quad \frac{1 \text{ cm}^3}{100 \text{ cm}^3/\text{sec}} = \frac{1}{100}\text{sec} = 0.01 \text{ sec}$$

This value, 0.01 sec or 10 msec, is approximately the duration of a single glottal period in an adult male voice. Thus, even if other factors are favorable to voicing, for example, the configuration of the vocal cords, a stop would become voiceless within about 10 msec of complete oral closure simply due to this aerodynamic constraint. This value would not change appreciably if smaller or larger starting values for air mass (oral volume) or glottal flow rate were used. But this cannot be the whole story, because voicing can be maintained in obstruents for a much longer interval

than 10 msec. An implicit assumption made in this calculation was that there was no expansion of the oral cavity. In fact, this is an unrealistic assumption. First, there can be 'passive' expansion due to the natural compliance or yielding of the walls of the vocal tract. Just like a balloon, the vocal tract 'gives' when pressure impinges on its surface. There is evidence that passive expansion allows voicing to continue during the closure of stops some 80 msec for labials, 65 msec for apicals, and 50 msec for velars – this variation correlates with the amount of surface area in the vocal tract behind the constriction which the air pressure impinges on. Second, there can be 'active' expansion of the vocal tract. The jaw and the larynx may be lowered in order to create more room for the air accumulating in the oral cavity. As one can infer from (9), voicing may be prolonged during a complete stop by about 10 msec for each 1 cm^3 of extra room created by expansion of the oral cavity.

Plausibly, the origin of voiced implosives in Sindhi can be traced in part to this constraint. As shown in Table 1, one of the principal sources of Sindhi implosives were earlier voiced geminate stops. Implosives, by definition, involve an active expansion of the vocal tract, one consequence of which is a lowering of oral pressure. One might imagine that the maintenance of voicing for the long interval required by gemination would entail active expansion. (However, due to subsequent phonetic change, the Sindhi implosives need not be fully voiced today.)

Another option in the face of the inhibition of voicing during geminate stops is to let them become voiceless. This is evident in the morphophonemic alternations from Nobiin (Southern) Nubian given in Table 2. Interestingly, the same data show that the devoicing does not affect labials, presumably because – as indicated above – they have the greatest surface area and thus the greatest potential for expansion during the closure.

A further reflection of the influence of place of articulation on the potential for continued voicing during stops may be found in the incidence of gaps in stops inventories. In most languages employing a voicing contrast, the voiced and voiceless stops appear in symmetrical pairs at each place of articulation (excluding glottal stops). But there are exceptions. Sherman (1975), in a review of the phonological descriptions of a controlled sample of languages, found 87 languages which made use of voicing in stops but which had one or more gaps in their stop inventories. Table 3 gives his results of the incidence of stop gaps tabulated by voicing and place. The table shows clearly that in the voiced series back-articulated stops are most often missing, presumably because they have less possibilities for expansion of the post-constriction space in order to accommodate the glottal airflow. (In the voiceless series, labials are most often missing, but this is probably due to their having no downstream resonating cavity and consequently very weak bursts.)

The same pattern holds for glottalic consonants, that is, among voiced implosives, velars are most often missing and among ejectives (necessarily voiceless), labials.

Voicing and Fricatives Following the reasoning presented so far, one might think that, although stops tend to inhibit voicing, there should be less of a problem regarding maintenance of voicing during fricatives because, instead of all the glottal air accumulating behind the constriction, some of it is vented. But in fact, fricatives appear to be an even less hospitable environment for voicing than stops; the asymmetry favoring voicelessness in fricatives is about three times larger than in stops. This does not mean that the reasoning about the effect of aerodynamic constraints on voicing in fricatives is wrong, rather that not only the requirements for voicing must be taken into account, but also those for frication. To optimize the aerodynamic conditions for voicing, we should have oral pressure, P_o, much less than subglottal pressure, P_s, that is, the difference in these pressures, ΔP_{glot}, should be maximized:

Table 1 Development of Sindhi implosives from Prakrit voiced geminate stops[a]

Prakrit	*Sindhi*	*Translation*
*pabba	paɓuɳi	lotus plant fruit
gaddaha	gaɗahu	donkey
-(g)gaṁtʰi†	ɠaɲɖʰi	knot
bʰagga	bʰaːɠu	fate

[a]Varyani (1974).
†This 'ṁ' is in the conventional transliteration of the Devanagari *anusvara* best regarded as symbolizing a nasal consonant homorganic to the following obstruent.

Table 2 Morphophonemic data from Nubian showing the effect of gemination and place of articulation on voicing[a]

Noun stem	*Stem + 'and'*	*Translation*
fab	fabːɔn	father
sɛgɛd	sɛgɛtːɔn	scorpion
kadz	kat tʃːɔn	donkey
mug	mʊkːɔn	dog

[a]Bell, W H (1971).

Table 3 Incidence of gaps in stop inventories according to place of articulation and voicing in 87 languages showing one or more missing stops[a]

	Labial	*Apical*	*Velar*
Voiceless	34	0	0
Voiced	2	21	40

[a]From Sherman (1975).

$$(10)\ \Delta P_{glot} = (P_s - P_o) = \max$$

But to optimize frication, we should have oral pressure much higher than atmospheric pressure, P_{atmos}, that is, the pressure drop across the oral constriction, ΔP_{oral}, should be maximized:

$$(11)\ \Delta P_{oral} = (P_o - P_{atmos}) = \max$$

One condition requires oral pressure to be as low as possible, the other to be as high as possible. Obviously both cannot be satisfied simultaneously. To the extent that voicing is maintained, the degree of frication is less than it might be; if frication is maximized, then voicing is threatened. In fact, it is well known that voiced fricatives always have less intense frication noise than their voiceless counterparts and on nonsibilant fricatives, for example, [β v ð ɣ], the frication is frequently so weak as to be barely detectable. Such sounds are often better described as frictionless continuants.

Frication

Approximants (glides) constitute narrowing of the vocal tract without inherently constituting obstruents. Nevertheless, they may cross the threshold into obstruents if produced with higher air flow.

The sonorant consonants [j w l ɹ], which by definition are nonobstruents, are usually voiced. However, simply by becoming voiceless, without any shift in the configuration of the oral articulators, they become the fricatives (and obstruents) [ç ʍ ɬ ɹ̥]. This happens due to the increased airflow passing through the narrow constriction created by these consonants – the increased airflow being caused by the greater opening at the glottis. It is possible to get a rough idea of why this happens. A typical approximant supraglottal opening, *A*, is 0.4 cm^2. When voiced, it might have a volume velocity, *U*, of 100 cm^3/sec. This would yield a particle velocity, v, as calculated in (12):

$$(12)\ v = \frac{U}{A} = \frac{100\ cm^3/sec}{0.4\ cm^2} = 250\ cm/sec$$

Now when this same approximant is made voiceless, the airflow increases substantially due to the open glottis, which lowers resistance to the expiratory flow; values of the order of 700 cm^3/sec would not be unusual. This would result in a much higher v and consequently greater turbulence:

$$(13)\ v = \frac{700\ cm^3/sec}{0.4\ cm^2} = 1750\ cm/sec$$

It is the higher volume velocity through the open glottis that leads to the higher particle velocity of the airflow through the supraglottal constriction, which leads to greater turbulence and, thus, the obstruent character of the voiceless approximant.

In the history of English and in contemporary dialects, there is evidence that sonorant approximants after stops (the position where they would be produced with higher airflow) have often resulted in fricatives or affricates. Historically *actual* had a palatal glide after the stem-final /t/: /ækt + juəl/; today the /tj/ sequence is realized as the affricate /tʃ/. Apical stop + *r* has a similar fate in some dialects of American English: *truck* [tʃɹʌk], *tree* [tʃɹi]. In initial position, the voiceless glottal fricative [h] is typically just a voiceless copy of whatever follows. Thus in English the [h] before the palatal approximant [j] is the palatal fricative [ç], for example, /hju/ = [çju] 'hue.' Similarly, in Tenango Otomi (Otomí, Tenango) (Blight and Pike, 1976) the phoneme /h/ is realized as a voiceless nasal before a nasal consonant, and as the fricatives [ɸ] and [ç] before /w/ and /j/, respectively.

There are many other sound patterns in language that can be traced directly, or indirectly to aerodynamic principles, including the phonetic factors that inhibit or facilitate spreading nasalization and the devoicing of vowels and glides. Some sophisticated computer models of speech aerodynamics have been devised and are being actively used by researchers interested in integrating phonetics and phonology.

Speech and Language Community

J T Irvine, University of Michigan, Ann Arbor, MI, USA

'Language community' and 'speech community' are constructs developed by scholars of language to refer to a social aggregate within which language is used. Over a century or more of discussion, scholars have differed as to whether the two terms referred to the same type of social formation or two different types. They have also differed as to whether the 'community' is to be understood as an empirically describable object in the world, or as an abstraction or idealization; whether to focus on speakers' knowledge or on their practice – or some combination; whether the aggregate should be considered from the perspective of its homogeneity or its internal diversity; and, most recently, whether the aggregate can be understood as a social whole – a bounded social universe – or whether it can only be understood as part of some larger field of social (and linguistic) relationships. Within these debates lurk different ontologies of language, society, and their relationship.

Briefly put, then, the problem of defining and identifying the speech community (and/or related terms) is both a theoretical and a methodological problem. The problem is theoretical because it concerns the locus and nature of the forces that shape language(s). What kinds of social relationship or grouping are implicated in what kinds of linguistic system, subsystem, or practice – and vice versa? Do the specifics of social organization matter, or is society no more than a prerequisite and general constraint on what really counts, a neuropsychology of language? The problem is methodological because it concerns where to locate and focus one's research. What is the arena within which to investigate how language is structured? Where should one look, to see how language takes form as social action?

Large though these questions loom in linguistic anthropology, outside this field they are not always seen as problematic. To some commentators it has seemed obvious that the 'speech community' must be an ethnic group that 'has' a single common language. This view is associated with the romantic nationalism of the late-18th-century scholar Johann Gottfried Herder, who maintained that a language is the natural hallmark, and the most precious possession, of a people (*Volk*) or nation, reflecting its special spirit and identity. To Herder's heirs, scholarly and lay, it has seemed natural to suppose that language itself creates – or automatically reflects – community: that there is always some aggregate of people who could be said to 'share' a language and who must, by virtue of that fact alone, share a cultural tradition, feel that they 'belong' together, and participate jointly in a social formation of some specifiable type – a people (or ethnic group, or nationality). In contrast, many linguistic anthropologists and sociolinguists problematize these connections, resisting the assumption that there is any 'natural' relationship between language and community that maps linguistic facts onto social groupings in some universal way. In arguments that have been foundational to our discipline, Franz Boas maintained that language, race, and culture are independent classifications of humankind, and that the distribution of particular linguistic forms does not necessarily predict the distribution of

Speech and Language Community

J T Irvine, University of Michigan, Ann Arbor, MI, USA

'Language community' and 'speech community' are constructs developed by scholars of language to refer to a social aggregate within which language is used. Over a century or more of discussion, scholars have differed as to whether the two terms referred to the same type of social formation or two different types. They have also differed as to whether the 'community' is to be understood as an empirically describable object in the world, or as an abstraction or idealization; whether to focus on speakers' knowledge or on their practice – or some combination; whether the aggregate should be considered from the perspective of its homogeneity or its internal diversity; and, most recently, whether the aggregate can be understood as a social whole – a bounded social universe – or whether it can only be understood as part of some larger field of social (and linguistic) relationships. Within these debates lurk different ontologies of language, society, and their relationship.

Briefly put, then, the problem of defining and identifying the speech community (and/or related terms) is both a theoretical and a methodological problem. The problem is theoretical because it concerns the locus and nature of the forces that shape language(s). What kinds of social relationship or grouping are implicated in what kinds of linguistic system, subsystem, or practice – and vice versa? Do the specifics of social organization matter, or is society no more than a prerequisite and general constraint on what really counts, a neuropsychology of language? The problem is methodological because it concerns where to locate and focus one's research. What is the arena within which to investigate how language is structured? Where should one look, to see how language takes form as social action?

Large though these questions loom in linguistic anthropology, outside this field they are not always seen as problematic. To some commentators it has seemed obvious that the 'speech community' must be an ethnic group that 'has' a single common language. This view is associated with the romantic nationalism of the late-18th-century scholar Johann Gottfried Herder, who maintained that a language is the natural hallmark, and the most precious possession, of a people (*Volk*) or nation, reflecting its special spirit and identity. To Herder's heirs, scholarly and lay, it has seemed natural to suppose that language itself creates – or automatically reflects – community: that there is always some aggregate of people who could be said to 'share' a language and who must, by virtue of that fact alone, share a cultural tradition, feel that they 'belong' together, and participate jointly in a social formation of some specifiable type – a people (or ethnic group, or nationality). In contrast, many linguistic anthropologists and sociolinguists problematize these connections, resisting the assumption that there is any 'natural' relationship between language and community that maps linguistic facts onto social groupings in some universal way. In arguments that have been foundational to our discipline, Franz Boas maintained that language, race, and culture are independent classifications of humankind, and that the distribution of particular linguistic forms does not necessarily predict the distribution of

other social and historical facts. Since Boas's time the issues under debate have become more subtle, but the central theme remains. How languages and linguistic varieties map onto people, activities, and social relations – and how the social constructs may depend on linguistic practice – are the central problems we must address, along with their constituent terms such as 'community of speakers.'

This article first traces two threads in the history of 20th-century scholarly writings on 'speech community,' up to approximately the 1970s. During this period scholarly debate turned on the relationship between individual and society, and on whether to focus attention on what members of a community have in common or on how they differ. I then turn to some more recent discussions and issues, such as the notion of 'communities of practice,' language's relation to social networks, distinctions between 'language community' and 'speech community,' and debates about the relevance of conflict-based (as opposed to consensus-based) social theories. Finally, I consider whether 'communities' can be conceived as wholes or only as parts.

The Homogeneous Speech Community

Let us begin with Ferdinand de Saussure's 'mass of speakers' (*masse parlante*, rendered as 'community of speakers' in the widely distributed Baskin translation of the 1916 *Course in general linguistics* [1966: 77, 78]). The *masse parlante* is the social collectivity that is necessary for language (*langue*) to exist in the real world. This collectivity is the foundation of the 'social fact,' the social conventions that establish linguistic signs as vehicles for semiosis. In emphasizing the social nature of language, and the importance of the 'social fact' for linguistic theory, Saussure moved away from the individualistic focus of some prominent earlier linguists such as the Neogrammarian Hermann Paul. For Saussure, language as a structured system is collective rather than individual, and because it is collective it is not subject to personal will or the vagaries of individual action. (The history of intellectual links between Saussure, Paul, and other scholars, particularly William Dwight Whitney, is actually more complex but need not concern us here.)

As a collectivity, Saussure's 'mass of speakers' is neither structured nor internally differentiated, and it has no social properties that would lead to differentiation in its participants' language (*langue*, the representation of linguistic structure). Instead, the collective consciousness exerts pressure on individuals to conform. All representations of language in individual brains are essentially alike, so that a language is like a book whose (virtually) identical copies are deposited in the minds of its speakers. According to the *Course* (Saussure, 1966: 13–14), "[language is] a grammatical system that has a potential existence in each brain, or more specifically, in the brains of a group of individuals. For language is not complete in any speaker; it exists perfectly only within a collectivity." As the locus of a synchronic collective consciousness, imagined as if extracted from time and action, the 'social mass' can only be an abstraction, a virtual community rather than a real one. (Later in the *Course*, Saussure suggests (1966: 223) that the 'linguistic community' is generally an ethnic unity. This passage stands quite apart from his discussion of linguistic structure, however.)

Readers today may find that Saussure's discussion of linguistic systematicity as a matter of mental representations in an abstract, undifferentiated virtual community has much in common with a well-known statement in Chomsky's *Aspects of the theory of syntax* (1965: 3): "Linguistic theory is concerned primarily with an ideal speaker-listener in a completely homogeneous speech community, who knows its language perfectly…" Like the *masse parlante*, Chomsky's speech community is an abstraction, not a misperception of an empirical world in which human communities are not perfectly homogeneous. In this view the speech community is little more than a precondition for language, whose locus – and here Chomsky departs from Saussure – is not in the collectivity but in the 'mind/brain' of the individual speaker. So strong is this emphasis on the biological individual, and so downplayed is the speech community, that linguistics is to be conceived as a branch of cognitive psychology.

In contrast to these views of the speech community as an idealization, Leonard Bloomfield's classic definition (in *Language*, 1933: 29) places the speech community in an empirical world of economic practicality that makes it homogeneous: "A group of people who use the same system of speech-signals is a **speech community**. Obviously, the value of language depends on people's using it in the same way" [emphasis original]. The value, that is, for a social division of labor where producers with different skills rely on a common code to coordinate the exchange of their products – or so Bloomfield supposed. Notice that this community is envisioned as socially and economically diverse, but uniform in (monolingual) language. Bloomfield's statement is about society as well as about language, and it makes an empirical claim.

How would this linguistic conformity come about? People who interact frequently will tend to speak alike, Bloomfield believed, because language acquisition is based on imitation and behavioral

conditioning. Arising out of the density of communication, which has made participants speak alike, a speech community would be distinguished from its neighbors by breaks in the frequency or intensity of interaction. (In practice, Bloomfield seems usually to have identified the speech community with a tribe or ethnic group – though not, incidentally, with a culture-bearing group, which he suggested was broader.) Within the community there can be 'lines of weakness,' slight differences in the frequency of interaction, corresponding to subgroups with slightly different forms of speech. As an example, Bloomfield cited Sapir's work on male and female speech in Yana. But although he mentioned that the differences between male and female speech in Yana are systematic – a point Sapir had stressed – Bloomfield did not discuss how 'lines of weakness' might give rise to differences that were systematic or conventional, rather than random. To propose that differentiation might be conventional would require the linguist to distinguish between the knowledge of linguistic forms and their use in acts of speaking, a distinction Bloomfield's behaviorist psychology did not easily support.

Anthropologists and linguists have long since discarded Bloomfield's behaviorist psychology of language. More durable, however, has been his notion that the speech community – the social site for linguistic description – is defined by interaction frequency. In his early works, John Gumperz identified the 'speech community' (or 'linguistic community' – in the early 1960s the terms were interchangeable) with some large social unit having a definite boundary around the outside and dense, frequent interaction inside. Unlike Bloomfield's, however, Gumperz's speech community could be multilingual. Its presumably dense interaction did not automatically produce homogeneity. So, in a study of a north Indian village, Gumperz (1958) suggested that Bloomfield's concept needed to be refined so as to distinguish between different kinds of communicative interaction: those that lead to behavioral convergence and those that do not. Despite regular patterns of interaction, the residents of this village did not all speak alike, and the study dealt with the social setting of these linguistic differences.

Similar lessons can be drawn from his work on convergence and creolization (Gumperz and Wilson, 1971), a study of language repertoires in a Maharashtran village whose population included speakers of Kannada, Telugu, Urdu, and Marathi. As a result of long-term proximity, the local varieties of these languages had changed, the authors concluded, in ways that made them more like each other. While the paper is justly known for this argument about grammatical convergence – even utterly unrelated languages may converge in several areas of linguistic structure if their speakers happen to live together for long enough – the convergence can only be described because other aspects of language have remained distinct. In fact, the villagers considered it important to maintain the linguistic distinctness of population subgroups in their multilingual community, and to differentiate between contexts of language use.

The Speech Community as the Organization of Diversity

As Gumperz's work illustrates, a new focus on linguistic diversity within communities began to emerge in the 1960s in studies of language contact, dialectology, and change. Led by Gumperz, Dell Hymes, Uriel Weinreich, and William Labov, the new work attacked the identification of structuredness with homogeneity (Weinreich *et al.*, 1968: 101). The speech community was now redefined as "a field of action where the distribution of linguistic variants is a reflection of social facts" (Gumperz, 1968: 383). Structure in the speech community rested on the organization of diversity, not merely on the replication of uniformity; its linguistic variation was not just random (Hymes, 1974: 75). The perspective recalls Durkheim's discussions of organic solidarity, where it is precisely people's complementary differences that bind them together, as opposed to mechanical solidarity, where social cohesion rests only on similarity. Thus multilingualism is not chaos, nor is it necessarily a transient or abnormal condition. Instead, it can represent an orderly social consensus.

This vision of speech community places multilingualism, multidialectalism, and communicative repertoires on center stage for observation and analysis, not on the periphery. The repertoire and its deployment in communicative practice are now seen as the crucial place where the relationship between language and social organization lies. Here we might observe how ways of speaking are linked with, and constitute, social groupings and identities, and how ways of speaking are situated in social activities. 'Community,' in the sense of sharing and commonality, lies in the interpretation, not the production, of behavioral forms (including speaking). What is shared is knowledge of how the differences in ways of speaking are organized.

As one of many examples, Hymes pointed to Paraguayan multilinguals who switch between Spanish and Guaraní according to the intimacy or distance of the communicative context. Gumperz (1964), meanwhile, compared the repertoires of two communities, one in India and one in Norway; the two communities' quite different social structures were

reflected in the different ways their linguistic repertoires were organized. In each community, members did not equally command all varieties, yet they understood when and where a code might be used – what its social implications were. Elsewhere, the Vaupés region of the northwest Amazon basin offers a particularly compelling example of the organization of linguistic diversity, since the social organization of the region has traditionally depended on a principle of linguistic exogamy: language is a badge of membership in one's patrilineal descent group, within which one may not marry. The marriage relationships that connected these groups and organized them in communities had to be contracted with persons whose linguistic 'badges' differed (see Jackson, 1974). Residential communities necessarily included spouses having different linguistic affiliations, and individuals were highly multilingual.

Notice, however, that if linguistic diversity does not prevent the formation of community in a social sense, then – by the same token – using the same language does not automatically create it. Illustrating this point, Gumperz (1979) described the communicative difficulties faced by a South Asian immigrant and a British interviewer. Despite the fact that their English was grammatically quite similar, the two interlocutors never succeeded in interpreting one another's responses, or in establishing a common understanding of the interview's purpose. As the example showed, using the same language (in the sense of 'denotational code') does not guarantee shared interpretation of the discourse's social import. Hymes (1968), meanwhile, in a survey of linguistic and anthropological literature, assembled a massive array of counterexamples challenging the Herderian assumption that common language reveals common ethnicity. Only in ideology must linguistic and ethnic boundaries coincide.

In the course of these arguments, Hymes and Gumperz sifted through some aspects of language and speaking that had often been assumed to coincide, yet (as they showed) could vary quite independently of one another. These distinctions must remain important in any adequate account of the social setting of linguistic practice:

- knowledge of a code (or, linguistic variety); i.e., the ability to interpret the denotational and predicational value of a symbolic system;
- behavior – the deployment of that code;
- claims to affiliation with a code, and claims to knowledge of it;
- knowledge of 'rules of use,' i.e., understanding the social distribution and appropriate deployment of codes.

Thus one might claim affiliation with a language one does not speak, as did an Italian-American student of mine who wrote a paper entitled 'Why can't I speak my language?' The Yana woman of Sapir's day could interpret all the forms of 'male speech' even if she never uttered them. (Actually, she might utter them if she quoted a male character while telling a story; but she would not produce these forms while speaking in her own social persona.) And rules of use may distinguish among addressees and contexts, even if the addressee does not reply in the same code – as when I reserve a special way of speaking for my pet cat's ears alone.

The recognition of linguistic diversity and its engagement with the structuring of social relations opened up vast areas of sociolinguistic research. As that research proceeded, however, and the sociolinguistic conception of speech community was to be operationalized, new questions arose. In particular, if speech communities are supposed to be objects of empirical description, how are they to be identified? If the community is delimited by some radius of shared knowledge, exactly what is shared? How much knowledge must be shared, and by whom? Recognizing that 'shared knowledge' can never be all-inclusive, Gumperz proposed that what the speech community shared was knowledge relevant to some significant number of social situations. But what is a significant number, and what makes a social situation significant? Consider, for example, gender-segregated initiation systems where initiates learn special linguistic varieties – such as male initiates in Walbiri and other societies of aboriginal Australia. Perhaps Walbiri women were aware that such varieties existed, but they were in no position to control them, or even to know the details of the appropriate situations of use. Some kinds of knowledge depend on a person's position in a social structure and access to situations in which a particular code is used.

To address this problem, one might envision a hierarchy of speech communities, or overlapping communities, depending on the scope of shared knowledge. In a study of creole language use in Guyana, Rickford (1986) pointed out that the ability to recognize linguistic indices of broad social categories was shared not only within the community of Cane Walk but also within larger communities, even in the whole country, while more subtle sociolinguistic meanings were known only more narrowly. The difference in social scale involved not only a difference in the amount and delicacy of sociolinguistic knowledge but also a difference in evaluative schemata. But if the 'speech community' is taken to delimit the social unit within which linguistic diversity is socially constituted and accounted for – an

empirical object that is also the locus of its own explanation – rather than marking the bounds of a particular study with specified goals, then speech communities may well **seem** to be discrete units, although it is only the researcher's approach that makes them so. It is tempting, moreover, for researchers to slip back into older notions of 'community' and to take a village, or an ethnic group – or a village as localized instantiation of ethnicity – as the sole unit of description.

Finally, how does one investigate knowledge, and how does one determine whether knowledge is shared? To what extent is the relevant knowledge available to conscious articulation, or is it embedded in practice? It is all too easy to take a few informants' claims as being an analysis of the relevant groups, varieties, and uses of language – and so to mistake a particular participant's ideology of language for a description and analysis. One solution has been to abjure informants' explicit analyses, except insofar as they identify some locality or grouping, such as a town or a neighborhood, within which to describe linguistic practices. This is the approach taken by Labov and his followers, who emphasize empirical reliability via consistent interview protocols and representative samples of community members. Labov's speech community (1972: 120–121) is defined not by members' producing the same linguistic forms in the same way, but rather by "participation in a set of shared norms; these norms may be observed in overt types of evaluative behavior, and by the uniformity of abstract patterns of variation which are invariant in respect to particular levels of usage." While 'shared norms' may suggest shared ideas and values, what looms larger in Labov's work are norms of use (statistical norms). It is the patterns of linguistic variation – i.e., overlapping patterns of usage, within a controlled sample of contexts – which he puts forward as the crucial evidence of participation in the speech community.

The speech community described in Labov's most recent book (2001) is Philadelphia, represented by samples of speakers from five neighborhoods and a random sample from the city telephone directory. These samples do not actually represent the city, however, because they were purposely restricted to American-born whites. Other speakers, including Philadelphia's large African-American and Latino populations, are excluded because, Labov argues (2001: 506), they do not share in the same patterns of linguistic variation. The purpose of the study, and rationale for the sampling decisions, was to explore linguistic change in the local vernacular English, not to describe all linguistic practice in the city. The question remains, however, as to whether the presence of nonwhite and nonnative speakers is or is not relevant to currents of change.

Observe that this 'speech community' is defined in terms of sharing in a particular pattern of language use – a single 'local vernacular' whose manifestation varies principally in whether a speaker is leading or lagging in its ongoing currents of change, and whether the speech situation is such as to reveal the vernacular most clearly. These variations distinguish among genders and socioeconomic classes within the set of native white Philadelphians, but it is only in that sense that they describe linguistic diversity. Whatever analysis one might envision of the linguistic practices of the city's broader ethnic and racial composition – an analysis that would need to consider multilingualism, multidialectalism, and the social organization of exclusion and avoidance – is precluded from this approach and this conception of 'speech community.' (One might ask, however, whether 'community' is the best rubric for the larger analysis.)

These questions about boundaries, sharing, and the relationship of meaning to practice have given rise to some alternative formulations of the object(s) of study. By the mid-1980s, ethnographically oriented scholars were beginning to reconsider the social theory underlying then-current analyses of linguistic repertoires and social actors, and to rethink concepts such as 'community' and 'class.'

Speech Networks and Communities of Practice

In a large city it cannot be taken for granted – as indeed it should not anywhere – that the social ties most relevant to linguistic practice are geographically concentrated. Residence, work, recreation, and other activities may be dispersed, and one person's set of social contacts may differ from another's. Network analysis, an approach first developed in urban anthropology and sociology, tracks the webs of personal relationships wherever they occur, starting from an individual and that person's interlocutors. The analysis collates and compares such person-anchored networks and considers how they may reflect or influence linguistic practice. For example, networks may be relatively closed (members have more contacts with each other than with outsiders) or relatively open (less overlap among individuals' social ties). In an early use of the network approach, Gumperz (1964) argued that these properties of networks accounted for differences between the linguistic repertoires of two communities, one in India and one in Norway. Another way to compare networks concerns whether ties are strong (multiplex – an individual has many kinds of relationship with the same

person) or weak (relating to the other person in only one situation). Lesley and James Milroy (1992, and elsewhere) have proposed – initially from research on linguistic variation in spoken English in inner-city neighborhoods in Belfast – that close-knit networks with many multiplex ties foster linguistic conservatism, while weak ties are vehicles of linguistic change. Emphasizing close-knit networks' importance as the site of (emergent) shared experience, Gumperz and the Milroys have linked them with notions of 'community,' although Gumperz also calls open networks 'communities' and maintains they still hold something in common.

A related construct is the 'community of practice,' a grouping that is based on participation in some activity or project. As with network analysis, the point is that any 'shared' understandings are accounted for as products of joint experience and coconstructed relationships. As Eckert and McConnell-Ginet write (1992: 464), "ways of doing things, ways of talking, beliefs, values, power relations – in short, practices – emerge in the course of this mutual endeavor." Participation in the activity, and members' definition of it, distinguish this grouping from older notions of community. This approach is especially useful, the authors find, for studying gendered language practices. Because activity-based groups such as football teams, armies, and boards of directors are likely to have a predominantly male membership, while secretarial pools and aerobics classes mainly draw women, these groups' distinctive linguistic practices easily become associated with gender (Eckert and McConnell-Ginet, 1992: 472). A focus on community of practice asks how an activity, a group, an individual as participant, and the meanings of linguistic practices mutually constitute one another.

Both these constructs, speech network and community of practice, suit a social theory in which 'community' is not assumed *a priori*; instead, it has to be achieved. Recently, Duranti (1997: 82) defined the speech community itself in this vein, as "the product of the communicative activities engaged in by a given group of people" – and the work of Ochs, Duranti, and their associates has emphasized the detailed study of activities and social interactions as communicative practices. This emphasis on the emergent character of social relations and the understandings connected with them resembles the ways many anthropologists have rethought the concept of 'culture.' Where older concepts of speech community, in their focus on the distribution of knowledge, presented a relatively static picture in which knowledge was unaffected by the action that applied it, discussions of community of practice and speech network permit a view of culture as public, negotiated, and located in interactional space rather than in a sort of mental museum.

Ideologized Representations and Imagined Communities

Eckert's mention of meaning and beliefs reminds us that sociolinguistic 'knowledge' is not just a tape recording of utterances, but an ordered, cognized, and filtered set of representations. Our interpretations of the linguistic practices around us depend not only on what is actually said, but also on stereotypes we have built up out of our experience – built and (re)configured (Agha, 1998; Irvine and Gal, 2000; Silverstein, 2003). Thus, in a discussion of honorific language in Tibetan, Javanese, and elsewhere, Agha shows how speakers' ideologies of deference, social hierarchy, and linguistic 'purity' lead to asymmetric distributions of linguistic forms across social categories – aristocrats and peasants, for example, deploy different constellations of forms – and these usages yield, in turn, stereotypes of speaker identity and rank (Agha, 1998: 166). Although Agha and Silverstein emphasize that the stereotypes are based on evidence – grounded in participants' discriminable experiences of language use – the stereotypes can also overwhelm the input, influencing the interpretation of utterances that do not precisely conform to them. Since people's experiences differ, and since interpretations also reflect the interpreter's position in society – and these differences pertain even to coparticipants in a particular activity group – cultural stereotypes and sociolinguistic knowledge cannot be perfectly 'shared.'

The object of study in this line of research reaches beyond the immediate. Distinguishing between representations that are experience near and those that are experience far, we must explore the latter in their own right. The people I imagine as co-inhabitants of my social world, including those I envision as past and as potential interlocutors – as well as those I know I will never meet and those I hope to avoid – are a population not limited to the history of my actual contacts. A recent strand of research on speech communities has considered these distant and imagined relationships. For example, Spitulnik (1996) examined the role of Zambian radio programs, whose audience may imagine itself a community of shared listening practices. In the circulation of 'public words,' such as catchphrases from well-known programs and announcers, listeners repeat the expressions that show their familiarity with the broadcast, and so constitute a colistenership with people they have never met. 'Hello Kitwe?' – a channel-checking expression with which the broadcaster based in the

Zambian capital tries to transfer operations to a broadcaster based in the provincial city Kitwe – when repeated in a crowded shop by a customer trying to get attention, arouses knowing smiles in other customers who recognize the phrase (Spitulnik 1996: 168).

The social groupings defined by the circulation of 'Hello Kitwe,' and by a radio broadcast's audience (actual or potential), are perhaps more often counted as 'publics' than as 'communities.' The terminological difference stems from the impersonal character of the 'public,' which is linked to its potentially large scale as an arena of communication and signals its connection with political institutions. As Gal and Woolard (2001: 1) wrote, "the work of linguistic representation produces not only individualized speakers and hearers as the agents of communication, but also larger, imagined social groupings, including . . . publics. Such representational processes are crucial aspects of power, figuring among the means for establishing inequality, imposing social hierarchy, and mobilizing political action." Our lives, including many aspects of linguistic practice, are affected by these representational processes and the actions they lead to, sometimes at a considerable distance.

Notice now that the publics imagined from different social standpoints may not define the same sets of people, and may fail to coincide with any concretely traceable social network. Zambian policy makers, like many others in Africa, distribute radio broadcasting – schedules and topics – among seven 'official Zambian languages' plus English, according to a model that equates language with ethnicity and region. Since most listeners are multilingual and some languages far outreach the ethnic populations they supposedly identify, actual audiences for a program are often quite different from the ethnic communities imagined in radio policy. Of course, the propensity to identify (homogeneous) language with ethnicity and region has a wide distribution and a long history, taking us back at least to the Herderian formulations mentioned early in this article. The same kind of equation underlies Benedict Anderson's otherwise brilliant discussion (1991) of the nation as 'imagined community' – imagined as the readership of newspapers and novels published in standardized languages and distributed via the mechanisms of print capitalism. As if it were an ethnic group writ large and mediated by print capitalism, this 'community' resembles the Saussurean homogeneous speech community in that Anderson assumes the population is monolingual in 'their' language, whose slight phonetic variations do not interfere with reading. This community is doubly imaginary, then – in its members' imagination and in Anderson's. It exists only in an ideology that imagines the standardized language of the nation-state as the common natural resource of its citizenry, so that linguistic diversity is interpreted either as something trivial, or as deviance and inadequacy. Images of the nation, and of the 'authentic' citizen, are at stake.

A good example is the debate over an orthography for Haitian Créole/Kreyòl (Schieffelin and Doucet, 1998). The spelling of the language's name illustrates the problem: the contest between those who see 'Créole' as fundamentally French – and speakers of standard French as the most authentic citizens – and those who see 'Kreyòl' as fundamentally other. The authors ask (1998: 303): "What is the real, authentic kreyòl? Thus, who is the real, authentic Haitian – the dominated 'Africanized' masses or the dominant 'Frenchified' elites? Is there a 'pure' kreyòl? . . . The sound system leads directly into the core of the debate about social classes, legitimacy, and authenticity."

Those who reject the Herderian formulation of language-based community must nevertheless recognize its prevalence in many parts of the world as the ideological grounds for political, territorial, and other kinds of claims. Silverstein (1996, 1998) therefore distinguished between 'language community,' which is based on its population's allegiance to norms of some 'shared' specified denotational code (such as a prescriptive standard) – conceived as 'their language' – and 'speech community,' based on indexical facts of repertoire deployment and their associated norms of use. The distinction recalls our two earlier threads in the conception of 'speech community,' the Saussurean and the sociolinguistic, but it places the former in the realm of ideologies of allegiance and the latter in the realm of situated experience. Although this pluralistic view of community is appropriate for many kinds of analysis, Silverstein (1996) showed its particular utility in understanding the dynamics of language contact in North American ethnohistory. The spread of European languages and their eventual dominance over indigenous ones took place within local settings which had varying social histories and shifting allegiances.

This analysis depends on looking at social (and linguistic) relationships of different kinds and on different scales. In the contact zone, indeed anywhere, 'language community' and 'speech community' do not identify the same population. Yet, the social dynamics of each kind of community affects the other. As Silverstein (1998: 401) put it, they are dialectically constituted cultural forms. Moreover, localized forms of speech and local social ties are in a similarly dialectical relationship with larger-scale, even global, currents. The proponents of *francophonie*, for example, must contend with local social dynamics and

multilingual scenes, while populations in localities as disparate as Québec and Rwanda contend, in turn, with *francophonie*'s language-based claims to their allegiance. The 'local' is itself an emergent construct, produced in relation to larger-scale processes. In sum, speech communities and language communities are different; neither stands alone; and an account of either must look outside its bounds.

The View across the Boundary

Questions about the speech community's boundary have already been raised with respect to the scale of analysis – a gradient in which face-to-face social groups, where everyone knows a great deal about everyone else, are embedded in larger settings where people are less well acquainted or not actually encountered at all. The question of boundaries is not just a matter of scale, however, but also of opposition. If, for example, boardrooms and Tupperware parties define different communities of practice and if they are associated with gender, then their relationship is one of opposition, not merely of random difference. And while it could be argued that gendered practices, however divergent they might be, are nevertheless part of some larger 'community' whole, any community X is only identifiable in relation to some population that is not-X. Even in face-to-face interaction, the participants establish their distinct identities as well as their commonalities.

Interaction is thus as much a process of differentiation as of accommodation. The crucial question is what kinds of differentiation and accommodation are produced, and by what semiotic means, in each empirical case. A similar question was asked decades ago about the signs distinguishing different ethnic groups. In *Ethnic groups and boundaries*, Fredrik Barth argued (1969: 10) that "ethnic distinctions do not depend on an absence of social interaction and acceptance." Instead, the persistence of an ethnic boundary depends on people's defining themselves in opposition to others whom they know. Similarly, Labov's classic research on Martha's Vineyard showed that the residents' speech forms were being reconfigured because – after the island's economy shifted away from fishing and toward the tourist trade – the contrast between native islanders and visiting mainlanders increasingly outweighed the islanders' internal divisions. Apparently, the Vineyard dialect was diverging from mainland speech because of, not in spite of, increased contact.

Following these precedents, Irvine and Gal (2000) argued that attention to boundaries and processes of differentiation should replace the concept of 'speech community,' which was overburdened with problematic baggage. Descriptions framed in terms of the 'speech community' tend to privilege a particular scale or type of social organization and to preclude exploring relationships that extend beyond its boundary. Moreover, many scholars now disavow the consensus-based social theory that underlay much earlier sociolinguistic and linguistic discussion of 'community' and discouraged attention to processes of exclusion, conflict, and domination. Rickford and the Milroys, for example, have proposed that conflict models of social class account better for the observed patterns of sociolinguistic variation than the consensus model can. In a related vein, Morgan (2003) argued that "speech communities are recognized as distinctive in relation to other speech communities.... They come into collective consciousness when there is a crisis of some sort, often triggered when hegemonic powers consider them a problem... Speech community represents the location of a group in society and its relationship to power." This emphasis on crises and power relations external to the community is borne out in Morgan's writings on the discursive practices of African-Americans, especially women.

Social life includes both agreement and conflict, sometimes both at once. In our joint work, Susan Gal and I have tried to capture this complexity by focusing on (linguistic) differentiation as a semiotic process that accommodates, but does not in itself entail, contestation. This complex process, we argue, includes a principle of fractal recursivity: an opposition that has been understood at one level of relationship can be projected onto other levels, yielding subcategories and supercategories. Thus the same process accounts for the possibility that linguistic varieties, social identities, or any other sociolinguistic formation may sometimes be seen as (sub)divided, but sometimes as unified. For example, in research on rural Wolof speech patterns I have proposed (Irvine, 1990) that a principle which (ideologically) distinguished the speech of high and low Wolof castes applied recursively. Applied within the high caste it marked subtler distinctions of rank; applied between languages it distinguished Wolof from French, to the latter's disadvantage.

We focus on differentiation because difference and distinction are what makes possible the logic of relations on which society and language depend. Just as Jakobson and Sapir showed for language, society too consists in relations and fields, not things. A focus on 'community' that does not look across the grouping's boundaries tends to obscure the relational logic that organizes a social field, by overemphasizing what people have in common and treating its object of study as an autonomous thing, rather than an artifact

of the researcher's approach. No community is an island.

Conclusion

Researchers investigating the relationships of language, culture, and social life need ways to think about the social aggregates in which those relationships are located. Most authors refer – whether loosely or rigorously – to some sort of 'community.' As we have seen, however, definitions of 'speech community' have varied widely, and many scholars now argue that it cannot be entirely self-contained as an object of study. Just as most anthropologists no longer see 'culture' as a homogeneous object that can exist in isolation (and should not be treated as if it did), we realize that speech communities are related to other social formations that intersect with them, or are incorporated within them, or contrast with them, or include them. A crucial step away from the speech-community-as-ethnic-island approach is to see language community as distinct from speech community, and the two in dynamic relationship – a step that puts the Herderian formulation in its (ideological) place.

Nevertheless, the word 'community' invokes an aura of consensus and common cause, even if you try to define it in some other way. It is tempting, therefore, for 'community' – whether researcher's or participant's construct – to conflate, or slide among, at least three quite different axes of relationship: homogeneity and difference, consensus and conflict, solidarity and distance. Just as difference is not the same thing as conflict, so any conflation of homogeneity, consensus, and solidarity under the rubric of 'community' is misleading. It is all the more so when language is added into the mix, as if languages were based upon – or could produce – these qualities of community. These issues ought to be disentangled.

Even if its technical utility is limited, however, 'community' is a term it is hard to do without. Its various formulations each address something of interest as to how the practices that make social relationships rely on systems of signs. Although the scholar who looks for standardized off-the-rack technical terms will not find one here, there is much to be gained from exploring the surrounding debates.

Introduction

This article addresses the *Representation* of Speech and Thought (henceforth RST). The overwhelming focus will be RST in literature, but many of the principles can be extended to the representation of speech – and even of thought – in other varieties and genres: journalism, records of parliamentary debates, commissions of inquiry and committees, police interviews, etc. Still it is worth noting at the outset that literary representation of speech and thought emerges from the potential in all written languages – a potential of inestimable value – to record ('capture', render inspectable) in semipermanent form (hence usable at later times and in different places) what someone said at one particular time and place. More remotely yet, written records of speech must derive, as a counterpart, from the reporting of others' communicative acts that is so important a part of spoken and sign languages.

RST is therefore bound up with writing rather more than is always acknowledged. Younger readers, fully of the digital age, may be puzzled that these opening remarks about the power to record or represent speech are not focused on audiotape recording and digitized sound files, now very widespread means of representing speech. But this article is about an affordance of the much earlier and more culture-changing technological breakthrough, the development of writing, and literary authors' rich repertoires of means for presenting characters' words on the page. Little further mention will be made of Internet literature or Web-based fiction; but it may be noted in passing that modern technology is such that there is nothing to stop a Web-based fiction writer from using sound files for some or indeed all of the discourse categories shortly to be described (characters' direct speech, indirect speech, narratorial discourse, etc.). One literary format of increasing importance that might here merit further comment is the audio novel, widely used by travelers and the print-weary: typically using just one performer as teller, they deserve fuller study to see how they resolve the tricky problem of conveying direct speech and the narratorial forms distinct from each other. And then how do they cope with those passages of FID or combined discourse (to be described later), where the voices of narrator and a character are impossibly mixed or calqued? Nowhere do Bakhtinian ideas of the polyphony or clash of voices seem more palpably applicable. The potential 'reoralization' of the written genres of the novel and the short story, triggered and sometime perhaps prompted by the spread of audio-books, may come to require extensive scholarly treatment.

RST, then, comprises some processes for the partial simulation of speech or thought that have emerged in written language. A general caveat at the outset: this article focuses on and takes its examples from

Introduction

This article addresses the *Representation* of Speech and Thought (henceforth RST). The overwhelming focus will be RST in literature, but many of the principles can be extended to the representation of speech – and even of thought – in other varieties and genres: journalism, records of parliamentary debates, commissions of inquiry and committees, police interviews, etc. Still it is worth noting at the outset that literary representation of speech and thought emerges from the potential in all written languages – a potential of inestimable value – to record ('capture', render inspectable) in semipermanent form (hence usable at later times and in different places) what someone said at one particular time and place. More remotely yet, written records of speech must derive, as a counterpart, from the reporting of others' communicative acts that is so important a part of spoken and sign languages.

RST is therefore bound up with writing rather more than is always acknowledged. Younger readers, fully of the digital age, may be puzzled that these opening remarks about the power to record or represent speech are not focused on audiotape recording and digitized sound files, now very widespread means of representing speech. But this article is about an affordance of the much earlier and more culture-changing technological breakthrough, the development of writing, and literary authors' rich repertoires of means for presenting characters' words on the page. Little further mention will be made of Internet literature or Web-based fiction; but it may be noted in passing that modern technology is such that there is nothing to stop a Web-based fiction writer from using sound files for some or indeed all of the discourse categories shortly to be described (characters' direct speech, indirect speech, narratorial discourse, etc.). One literary format of increasing importance that might here merit further comment is the audio novel, widely used by travelers and the print-weary: typically using just one performer as teller, they deserve fuller study to see how they resolve the tricky problem of conveying direct speech and the narratorial forms distinct from each other. And then how do they cope with those passages of FID or combined discourse (to be described later), where the voices of narrator and a character are impossibly mixed or calqued? Nowhere do Bakhtinian ideas of the polyphony or clash of voices seem more palpably applicable. The potential 'reoralization' of the written genres of the novel and the short story, triggered and sometime perhaps prompted by the spread of audio-books, may come to require extensive scholarly treatment.

RST, then, comprises some processes for the partial simulation of speech or thought that have emerged in written language. A general caveat at the outset: this article focuses on and takes its examples from

literature in English, although there is no reason to suppose that RST and its subtle subtypes do not flourish in all the languages with a developed literary tradition; certainly it has been extensively studied and discussed in most European languages, and cross-linguistic studies are increasingly proposed, where much of the interest lies in comparing and contrasting the formal exponents of distinct subtypes (in particular the tense-aspect requirements in FID) and indeed whether certain subtypes are prominent in one literature while nonexistent in another, or developed much later, and so on.

Direct Speech and Indirect Speech

Direct Speech

> "My dear Mr. Bennet," said his lady [Mrs Bennet] to him one day, "have you heard that Netherfield Park is let at last?"
> Mr. Bennet replied that he had not. (Jane Austen, *Pride and prejudice*, chap. 1)

In the canonical forms of both direct and indirect speech today (henceforth DS and IS, respectively), a fundamental distinction is made between the reporting or inquit clause, in which the speaker of the reported material is identified and cast as the subject of a verb of communication, and the reported clause, in which that speaker's message is presented. The reported clause of direct speech is usually set off, by speech marks at its boundaries, from the reporting clause; and sentence-initial reporting clauses may be followed by a comma or colon. The reported clause is understood to give the speaker's actual words, *verbatim*, hence all the deictic elements (pronouns, tense, time and place expressions) within the clause or fragment reflect the speaker's deictic center, at the time of speaking, as in Mrs Bennet's speech. Here, the present tense is used for events/states that are true at the time of Mrs Bennet's speaking, she denotes herself by first-person pronouns (here *my*) and her addressee by second person pronouns, and all evaluations (*My dear … at last*) are entirely hers. Mr Bennet's reply is rendered in IS – which specifically denotes the segment *that he had not* – and this, like the reporting clause *Mr Bennet replied* that precedes it, is wholly based on the narrator's deictic perspective and as a result uses a third-person pronoun to denote the reported speaker and past tense. Various DS features are difficult or impossible in IS; here, for example, if Mr Bennet had echoed his wife's formulaic endearment this would be problematic within an IS construction:

> ? Mr. Bennet replied that (his) dear Mrs Bennet, he had not.

Terms like 'difficult' and 'problematic' are often applied here, where in canonical DS and IS the linguist is usually quite prepared to specify what is grammatical or ungrammatical. The manipulations of what is possible or acceptable in variant free forms of IS (in modern English at least) make firm grammaticality judgments particularly difficult in this area.

The reporting clause in DS can follow the reported speech, and in such cases there is scope for inversion of the verb and (usually) nonpronominal subject in the reporting clause. Or the reporting clause is 'flanked' on either side by direct speech:

> "Kitty has no discretion in her coughs," said her father; "she times them ill." (*Pride and prejudice*, chap. 2)

In present-tense feature-article journalistic reporting, such inversion within the reporting clause is frequent and possible even where that inquit clause comes first (again, provided the subject is nonpronominal):

> Adds Smith, "The key to utilizing a mammogram to its fullest potential is by getting a high-quality screening performed by a competent clinician … ." (*USA Today* 19 July 2001)

Although opening and closing inverted commas remain a standard marker of direct speech in all written varieties, many 20th-century fiction writers dispense with them, instead marking the onset of a character's turn of talk by a new line, an indent, and a long dash. But for those writers who retain reporting clauses with direct speech, it is important to note that they provide more than a perfunctory speaker-attribution: they often carry information about the speaker's emotions or attitude and may include information about gesture, facial expression, or body movement, all of which may be evaluative or indexical.

Indirect Speech

Whereas DS supplies the reported speaker's actual wording, IS relays only the content, gist, or illocution of the actual or implied DS utterance (implied in all cases of fictional IS, where there is no actual DS precursor). In indirect speech with a sentence-initial reporting clause, no graphic devices set off the reported material from the reporting clause, but the reported clause is introduced by a complementizer or subordinator (commonest is *that*, as in the Austen sentence above: *Mr. Bennet replied that he had not*). Where the reporting clause comes first, as in this example, complementizing *that* is often ellipted (cf. obligatory *que* in comparable French constructions), whereas more semantically specific ones cannot be: *if*, *whether*, and *wh*-words introducing indirect questions and exclamations. In the case of IS reports of

requests and other directives, *that* may or must be replaced by an infinitival construction, with raised reported clause subject: compare *She asked that he shut the door / She asked him to shut the door* and *She told him to leave at once/ *She told that he leave at once*.

The reported clause gives a version, and not the precise wording, of the original speaker's utterance, but all deictic elements now conform to the spatio-temporal coordinates of the narrator or reporter, already responsible for the reporting clause. Thus the original speaker of the reported clause is now denoted by third-person pronouns, and time and place expressions are to be interpreted relative to the narrator/reporter.

(1) Mrs Bennet asked whether he had heard that Netherfield Park was let at last.

The grammar of IS entails a wholesale adoption of the deictic orientation of the narrator. All deictic indicators that might appear in a character's direct utterance, keyed to the character's assumed point in space and time (in addition to tense and personal pronouns, words like *here*, *today*, *this*, and *now*), will be displaced by deictic indicators, which makes sense from the narrator's perspective (typically, the 'nonproximate' deictic forms: *there*, *on that (same) day*, *that*, *then*). Among the deictic indicators must be included the use in DS of a few verbs of specific directional movement, implying movement toward or away from the speaking character (*Come here!*; *Go away!*); by contrast in IS the movement verbs will be directionally nonspecific or, like other deictic elements, oriented to the narrator.

Although DS and IS are in a sense equivalent and - alternative forms, there are also asymmetries involved, particularly in fictional and literary contexts. For example, normally a conversational utterance will have just one DS form, but may have several IS versions, varying from each other in minor ways. Compare (1) above with other IS versions, (2) and (3):

(2) Mrs Bennet asked whether Mr Bennet had heard that Netherfield Park had finally been let.

(3) Mrs Bennet asked her husband whether he had been told that someone had finally taken Netherfield Park.

By the same token, when contemplating an IS sentence, several distinct possible DS versions can be proposed, without any certainty as to which if any was the actual source: any of (1), (2), or (3) could 'derive' from the following (among others) rather than Austen's actual formulation above:

(1)' Mrs Bennet said "Have you heard that Netherfield Park has been rented at last?"

It should be stressed that such variations of 'source' (DS) or of 'derived' (IS) forms are particularly associated with fictional narrative (where, for example, there simply is no actual DS counterpart of the IS construction that the writer has composed). In nonfictional contexts, the *vraisemblance* or 'faithfulness' standard may be set much higher, so that IS reporting of speakers may be required or expected to match closely the wording of the real DS source, to limit misrepresentation. In extreme cases or genres (e.g., when giving witness evidence in a criminal trial), IS may be disallowed.

When contemplating Direct Speech (and to diminishing degrees when considering each of the other forms to be discussed in this article), at least two binary distinctions need to be considered: is the text in which it appears literature or nonliterary; and is it hypothetical or actual (e.g., fictional DS may be used in philosophical and moral arguments). On that basis we can distinguish DS in novels and in philosophical arguments, letters recording personal experience, and hard news journalism or Hansard-like parliamentary records. The literary-and-actual is a less-exploited category, but there are enough novels that incorporate if only fleetingly famous individuals and some of their reliably documented utterances for this to be a real category. What distinguishes the nonliterary and actual from the literary and the hypothetical is that there is some process of transcription prominent in the former, and by contrast some kind of invention prominent in the latter (although neither variety is *purely* transcriptional or inventive).

Some Major Points of Difference between Direct and Indirect Speech

Indirect discourse maintains the tense of the encompassing narrative (in traditional English fiction, this is past tense; in some contemporary literature, this may be present tense). Direct discourse is in present tense, the norm for natural conversation of which it is a simulation. First- and second-person pronouns in the direct version, denoting the speaking character and their addressees, contrast with gender-appropriate third-person pronouns in the indirect version, being the narratorial designations of those characters (a large exception to this are those stories where the narrator is also a story participant and is accordingly designated within the story by first-person pronouns; a rarer exception are 'you-narratives'; but even in these exceptions, the pronouns denoting addressees, in the former case, and those for seemingly representing the narrator, in the latter case, diverge from the

direct I-you pattern. The two patterns are *I-him/her/them* and *you-[all accusative forms]* respectively. One general upshot is that English indirect forms are more explicit than the direct ones with respect to the gender of the addresser and addressee.

It has been traditional to describe the reporting and reported clauses in DS and IS as syntactically related to each other differently; in typical IS where the reporting clause comes first, they are syntactically related hypotactically, with a clear sense of matrix and embedded clause; but in DS the relation is paratactic, with the reported clause as nonembedded complement. But the most suitable grammatical description is certainly a matter of debate (see Huddleston and Pullum, 2002: 1023–30, for arguments). But it is clear that 'robustly paratactic' DS constructions, such as imperatives and exclamatives, resist incorporation into IS format. Thus when in Joyce's 'The Dead' Mr Brown takes a first sip of his whiskey and the text runs (using DS):

-God help me, he said, smiling, it's the doctor's orders.

it is hard to devise a truly plausible IS version:

?/* He smilingly cried that God should help him but it was the doctor's orders.
?/* God would help him, he said, it was the doctor's orders.

None of the 'colorful' idiosyncratic and dialectal qualities of the speech or thought of a character who is reported directly survive the transfer to a canonical IS version; the speech undergoes a kind of translation, into the language of the narrator, and the latter is conventionally (but not obligatorily) 'standard', 'neutral', detached, a superior knower even if they do not assert 'omniscience'. The narrator is sole authority, solely responsible, for the wording of both components, reporting and reported, of the IS construction. By contrast there is an explicit division of authority in DS constructions, with the reported speaker solely responsible not merely for the sense but also the actual wording of the reported material.

Still, it is worth emphasizing that what is certainly lost, in IS reporting, is not 'colorful language' necessarily, but 'the *character's* (possibly colorful) language'. That is to say, typically and conventionally, especially in literary fiction, narrators are more 'neutral' and formal than the characters of whom they tell. But this is only a convention or pronounced tendency and will be overridden in many particular cases. One is the novel *The adventures of Huckleberry Finn*, where Huck himself, as first-person narrator, reports nonstandardly the presumably standard speech of some of the protagonists in his story.

A Minor Variant of Direct Speech: Free Direct Speech

Where direct speech is presented without accompanying a reporting clause, it is given the more specific label free direct speech (FDS) by some analysts. In just this respect (lack of the reporting, inquit or 'framing' clause), FDS is like FIS, but in other respects it is really only a variant of DS (no difference is assumed or demonstrable between the exact content of DS and FDS versions) and not an independent category as the free indirect ones are. Reflecting its status as a variant, there are only slightly different functions or effects achieved by FDS that are not achieved by all DS. An alternative conceptualization would be to note that, unlike IS, the *inquit* clause is not essential or integral to a direct speech report, and that therefore those direct speech reports with a framing clause are the supplementary variant (ADS – attributed direct speech, in contrast with the unattributed form, which might now be labeled simply DS).

Often in cases of FDS the reporting clause is as close as the adjacent sentence. Or one reporting clause introduces (hence has 'scope' over) a series of (distinct) utterances from an individual, so that the technically FDS sentences are so created for purposes of textual economy as in ellipsis cohesion. More interesting may be sequences of FDS dialogue, typically between two parties (metronomic speech), where speaker change and speaker identification must be inferred by the reader, and with less than full certainty. Where DS has the reporting clause following, some analysts label the speech FDS, by analogy with parenthetical framing clauses in FID (see following).

Free direct speech may also be exploited to give the impression of rapid interchanges (as in fictional dialogue in Hemingway, Ivy Compton Burnett, etc.). Constructions that have the appearance of DS are widely used in print newspaper headlines (particularly tabloids), although it often transpires that the 'speech' is the creation of a copy editor who has rephrased one participant's most forceful remarks in more pithy and dramatic style or has synthesized the more subtly expressed views of several protagonists. By convention strict fidelity to the speaker's precise words is not always expected or required, but misrepresentation and trivialization are recurrent risks in this pursuit of entertaining, sales-generating copy.

NRSA and NV

Two categories have been proposed (by Semino and Short, 2004) as lying at the most indirect end of the speech representation continuum: these are

NRSA, narrative report of speech acts, and NV, narrator's representation of voice. The former, a more established and accepted category, equivalent to what McHale (1978) called 'diegetic summary', covers those reports of speech in which the content is severely abridged (to the point where arguably there is no genuine speech representation) but a scant indication of the type of illocutionary or perlocutionary force of the act is provided:

> All evening they argued and quarreled over how best to economize.
> Mary's father stepped in with congratulations. (Graham Greene, *Brighton rock*, p. 137)

As the most indirect form of speech representation, NRSA is a useful device for novelists who wish to keep firm control on the narrative, but at the cost of creating a non-scenic detachment from the living voices of particular speaking characters. NRSA is suited to an aggregative and abridged recording of views, particularly where these are in broad agreement, as in summarizing the view of a committee or even a large meeting

> [For hours] 8,000 hunt supporters . . . made themselves heard . . . . They vowed to go on protesting until the government reversed its plan to ban hunting with dogs. (*The Guardian*, 29 September 2004)

Whereas in NRSA utterances one arguably reaches the limit of speech representation, often with only a slight indication of the actual wording of the anterior speech, with NV (narrator's representation of voice) attention has turned away from representation altogether, to simply reporting that the activity of talking has occurred. NV covers those occasions where the narrative reports that an individual spoke, but "we are not given any explicit indication as to what speech acts were performed, let alone what the form and content of the utterances were" (Semino and Short, 2004: 44), or there is "summary reference to speech events that involved a large number of participants" (Semino and Short, 2004: 45). This new category (and even more so its near equivalent in thought-reporting, NI, discussed later) proved useful to Semino and Short, whose interest was in a corpus-based comparative study of frequencies of distinct types of category-use in a corpus of fiction, journalism, and (auto)biography. Two NV examples are given in bold here:

> We **exchanged a few words lazily.** (Conrad, *Heart of darkness*, p. 28)
> **After talks in Belgrade**, Mr Milosevic said he fully agreed with the international peace plan. ('Milosevic backs Hurd peace plea', *Guardian*, 5 December 1994)

Free Indirect Speech

> A conversation then ensued, on not unfamiliar lines. Miss Bartlett was, after all, a wee bit tired, and thought they had better spend the morning settling in; unless Lucy would at all like to go out? Lucy would rather like to go out, as it was her first day in Florence, but of course, she could go alone. Miss Bartlett could not allow this. Of course she would accompany Lucy everywhere. Oh, certainly not; Lucy would stop with her cousin. Oh, no! That would never do! Oh yes! (E. M. Forster, *A room with a view*, Penguin, p. 36)

At this point we must turn to the phenomenon that alone justifies dwelling on the topic of RST at such length in an encylopaedia of linguistics – a phenomenon interest in which, as a topic of some theoretical importance to linguistics, was greatly stimulated by German scholars of the Sprachseele school and linguists such as Charles Bally and Marguerite Lips in the early 20th century, the latter calling it *le style indirect libre*. Since then this narratological hybrid, lying somewhere between but apart from either the wholly narrated, or the reported, or the direct representation of speech, has acquired many names in different languages, including: *erlebte Rede*, represented speech, combined discourse, quasi-direct discourse, and free indirect speech (FIS).

FIS is the narratorially most fascinating of styles of discourse reporting, carrying some of the formal features of both character-expressive DS and narrator-expressive IS. FIS is a blending of the IS or narratorial options for tense, pronouns, and graphological non-removedness, but the DS or characterological options in syntax (especially noticeable in interrogatives and imperatives and exclamations), in its dispensing with complementizers, and its adoption of the character's space/time deixis, expressive lexis, and subjective modality.

But FIS is not simply a judicious combination of DS and IS features, nor simply some middle way between these two. Both DS and IS are accompanied by a framing or matrix clause: canonical FIS eschews one altogether (noncanonical FIS, with reporting clause present, is discussed later). Thus FIS is 'a bit of both' DS and IS, but also 'a bit of neither'. FIS styles of speech representation, then, are neither direct nor indirect according to orthodox prescriptions, but mixings or mergings of narratorial indirectness with characterological directness. And despite the earlier comparisons with DS and IS, the mode that FIS most crucially complements or contrasts with is PN (pure narrative: pure in the sense of being the narrator's direct address of the reader, without any traces of the words actually spoken or thought by characters; hence PN is chiefly reports of events and

actions, and descriptions). Where uncertainty arises for the reader in the evaluating of possibly FIS phrasings, the confusion is one between character voicing and narratorial voicing. Between DS, IS, and FIS we finally have only variations in the fullness or editedness of rendering of the same individual's voice; but where we cope with the risk of confusing FIS and PN we are in danger of misattributing or misidentifying two entirely different voices and two different individuals, the character and the narrator.

If there is one linguistic feature that seems noticeably more prominent in FIS than in alternative modes of discourse representation, it is modality. FIS is marked by frequent use of modal verbs (*must*, *should*, *had to*, *could*, *might*, *would*) and sentence adverbials (*certainly*, *perhaps*, *maybe*, *surely*, *of course*, etc.) expressing judgments about the likelihood or necessity or desirability of some action or state transpiring. All such modality discloses the character's needs and wants and is frequently woven into contestable judgments. Postponing further discussion of the functions of FIS to a more inclusive section on FID generally, we turn to cases of indirect speech report with parenthetical inquit verb.

Preposed Reported Clauses: IS or FIS?

Of considerable interest are all cases where the reporting clause follows the reported one, and the latter has the 'backshifted' tense and distal or narratorial deictics that would suggest IS:

Could he accompany her home, he asked.
What an appalling summer she was having, she said.

These are not standard IS: both have, in the reported component, the syntactic inversions of direct questions and exclamations respectively, whereas with framing-clause-first IS noninversion of elements is the norm. Neither of the two cited sentences, if simply reversed, would be regarded as canonical IS, particularly in light of more grammatically unified alternatives. Thus both

He asked could he accompany her home.
She said what an appalling summer she was having.

would be judged nonstandard or dialectal, by contrast with 'standard' IS:

He asked if he could accompany her home.
She said that she was having an appalling summer.

But whereas *He asked could he accompany her home* might be classed simply as nonstandard IS, there are grounds for treating *Could he accompany her home (he asked)* as FIS, the belated reporting clause being processed by the reader only when the reported speech has already been understood to express the words and 'voice' of the character denoted by *he*, albeit expressed within the narratorial deictic regimen. As for the treating of *He asked could he accompany her home* as nonstandard IS, again it is hard to see a definitive formal or criterial basis for specifying where such nonstandard IS shades into some form of FIS (consider more character-expressive versions such as *He asked could he please please please accompany her home*).

Returning to the 'standard' IS sentences earlier, with reporting clause first, it is evident that a 'mechanical' inversion of the reporting and reported clauses of the kind possible in relation to DS utterances (She said "I'm lost!" ⇔ "I'm lost!" she said) yields ungrammatical forms:

*If he could accompany her home, he asked.
*That she was having an appalling summer, she said.

To be grammatical, the complementizer must be removed, and subject–verb inversion must apply in the reported question, but those steps move the reported clauses closer to direct speech, i.e., into the notional territory of FIS, than would otherwise be the case. And like FIS and DS sentences (and unlike those in IS) the reported clauses are also grammatically independent. One is drawn to conclude that where speech is reported using the narrator's tense and pronoun selections and with the reported clause preceding the inquit clause, there is no option of normal IS, and the only reason for withholding the label FIS from such cases would be adherence to the view, as axiomatic, that any within-sentence *inquit* clause cancels free indirect status.

Representation of Thought: Direct, Indirect, Free Indirect

Direct and Indirect Thought

In English literary fiction, all the speech representation categories discussed above have become matched, over the last 200 years or so, by loosely equivalent ones for the representation of thought. Indirect thought was the first to become widespread, but it is convenient to begin with direct thought (DT), which purports to give an accurate record of a character's verbalized thoughts. And like DS, which tends to be far more coherent, free of the repetitions, false starts, and other phenomena reflective of limited planning time than actual speech, so DT also, by convention, denotes a form of thought reporting that observes the norms of sentential grammar (e.g., expressing 'complete' ideas or propositions).

> He looked very tall on the darkening grass, and the thought crossed her mind, "He is like a weed." (K. Mansfield, *At the bay*, chap. 1)

> She looked up at the pale sky, and all she thought was, "Yes, it was the most successful party." (K. Mansfield, 'The garden party')

DT is used for self-addressed, self-instructing conclusions, at moments of crisis, high emotion, and revelation. In the reporting frame, forms of the verb *think* are commonest, but other verbs and formulations are found, including *say* without a reflexive pronoun. In context, Elizabeth Bennet's words that follow are clearly DT:

> With the mention of Derbyshire there were many ideas connected. It was impossible for her to see the word without thinking of Pemberley and its owner. "But surely," said she, "I may enter his county without impunity, and rob it of a few petrified spars without his perceiving me." (*Pride and prejudice*, chap. 42)

Like all thought-reports, DT is indicative of a narrator who is 'intrusive' and even 'omniscient' (although the suitability of the latter term is now much debated), one who claims and demonstrates exceptional inward knowledge of characters' minds and motives. Even in fiction, 'full' DT with reporting clause preceding is rare; less rare is DT with the reporting clause falling medially (as above) or later, so that the construction is partly or wholly FDT. Unlike Austen in the preceding example, few writers use quotation marks or even an indented new line to mark off the DT from any reporting of its source.

As noted earlier, DT is normally reserved as a label to describe text that represents character-expressive thought, but does so while conforming to the prescriptions of standard grammar, without abrupt fractures or jumps in the flow of structure or sense. Where those constraints seem to be absent, and we feel we are reading a transcript of the mind uncensored and unedited and freely associating, it is customary to refer to this mode as interior monologue (or 'very free' direct thought); literary critics often call it 'stream of consciousness'. In the novels of Woolf and Joyce, and especially in the latter's *Ulysses*, extensive direct thought of this kind is deployed brilliantly, to characterize individuals in all the fecundity and heterogeneity of their thoughts and desires; the mode is exceptionally effective in displaying and dramatizing the depth of human reflexivity – our ability to think about several things at once, to see significance or mutual relevance in disparate things, and to think *about* how we think about such things. Here, for example, is the opening of Molly Bloom's famous interior monologue, which comes at the end of *Ulysses*:

> Yes because he never did a thing like that before as ask to get his breakfast in bed with a couple of eggs since the City Arms hotel when he used to be pretending to be laid up with a sick voice doing his highness to make himself interesting for that old faggot Mrs Riordan that he thought he had a great leg of and she never left us a farthing all for masses for herself and her soul greatest miser ever was actually afraid to lay out 4d for her methylated spirit telling me all her ailments she had too much old chat in her about politics and earthquakes and the end of the world let us have a bit of fun first God help the world if all the women were her sort down on bathingsuits and lownecks of course nobody wanted her to wear them I suppose she was pious because no man would look at her twice. (Joyce, *Ulysses*)

Indirect Thought

As in IS, in indirect thought there is a framing or reporting clause identifying the individual who is the source of the reflection, and a following clause of reported thought.

> She blushed at the very idea [of accidentally meeting Mr. Darcy], and thought it would be better to speak openly to her aunt than to run such a risk. (*Pride and prejudice*, chap. 42)

Constructions of this form, in the narration rather than within direct speech, with initial reporting clause, are not particularly frequent in literature – especially when one has excluded instances (such as the following, in bold) that in context are IS and not IT:

> Mr. Bartell D'Arcy . . . praised very highly the leading contralto of the company but Miss Furlong thought **she had a rather vulgar style of production**. (Joyce, 'The dead')

In many constructions, the reporting clause is followed by something – e.g., a preposition – rather than the default subordinator *that,* and this preposition is in turn perhaps followed by a nonfinite clause or only a phrase: *she wondered at . . . , he thought of the way . . . , she told herself of*, etc.

> He thought of how she who lay beside him had locked in her heart for so many years that image of her lover's eyes when he had told her that he did not wish to live. (Joyce, "The dead")

In such cases, the passage may be felt to be shading toward the 'more indirect' mode than that of IT, namely NRTA (see later discussion), with its more summarized or rephrased representation of a character's thoughts. As in the cases of IS with noninitial reporting clause discussed earlier, it is often more appropriate to classify as free indirect thought (FIT) those cases of apparent indirect thought report where the reporting clause is medial or final. In the first of

the following examples, the FIT status of the bolded words is supported by the fact that in the context the preceding sentences are also clearly Mrs Ramsay's FIT rather than narratorial:

> No. He could not say it right. He could not feel it right. **But why not?** she wondered. (Woolf, *To the lighthouse,* Penguin, p. 16)

> Odious little man, thought Mrs Ramsay, why go on saying that? (Woolf, *To the lighthouse,* p. 19)

Free Indirect Thought

As in FIS, FIT combines linguistic markers reflective of the narratorial function (such as narrative tense, use of pronouns as if participants are being named from the narrator's point of view) with some or all of the expressive and subjective reflections of the character's voice (here, in the realm of thought, the character's 'inner' voice). Like FIS, the additional absence (in nearly all cases) of a governing, utterance-initial reporting clause is important. The text therefore has some of the appearance of narrative, but in the detail it is very much a voicing of the character's mentality, in the character's words. And, again, the absence of reporting clause erases some of the impression of clear hierarchy, of an external teller and an observed character being told about. The sense of thoughts being reported is displaced by a sense of thoughts being disclosed, of mental reaction and reflection shown in the course of its being experienced. A very powerful effect of alignment of narrator and character can be achieved, if fleetingly: FIT is, it should be stressed, a relational category: it often draws its strength from its difference from adjacent Narrative, DT, or IT material:

> The possibility of meeting Mr. Darcy, while viewing the place, instantly occurred. **It would be dreadful!** She blushed at the very idea, and thought it would be better to speak openly to her aunt than to run such a risk. (Austen, *Pride and prejudice*, End of chap. 42)
> It seemed to her such nonsense – inventing differences, when **people, heaven knows, were different enough without that**. **The real differences**, she thought, standing by the drawing-room window, **are enough, quite enough**. (Woolf, *To the lighthouse*, Penguin, p. 13)

And there is always something necessarily surreptitious and covert about it, by comparison with its neighboring types: the latter through punctuation and reporting clauses and tense and pronoun forms make quite explicit their direct or indirect status, respectively. Like DT, FIT is used for moments of heightened emotion or insight or resolve, but also for moments or thoughts that are implicitly buried deeper within the character's psyche than DT material, and thus less amenable to full-sentence first-person expression – in some cases, sufficiently deeply buried that (we infer) the character will not go on record as explicit source of the thought.

It has become customary to talk of the 'free' in FDS, FIT and so on, as meaning 'free of a framing clause in which who speaks or thinks is explicitly identified'; but in practice one encounters degrees of freedom. On the one hand a parenthetical reporting clause does not govern, syntactically, whatever clause precedes it, and such clauses can have all or some of the word-order, deixis, modality and lexical subjectivity of the character in quasi-direct form, to the point that readers will confirm that the 'voice' or intonation of the character seems to predominate: largely free, then, at least until the reporting clause is encountered. On the other hand many grammatically complete utterances that combine character expressivity with narratorial tense- and pronoun-selections – thus, canonical FIT or FIS – have explicit indications, in adjacent sentences, of the particular character who is the source of the thoughts or speech: only free very locally, then, and not when cotext is fully taken into consideration. Ultimately those occasions of FID and FDD that are of most interest to literary linguists are those where uncertainty over the answer to the question 'who speaks here, who thinks here?' persists even after a thorough rereading – where some ambiguity remains as to whether a judgment or insight is the narrator's or the character's, or that of one character and not another. And such uncertainties are often connected to the content and intent of the represented comment or judgment: if this appalling remark was intended seriously it must be from the character, but if intended ironically it is probably the narrator's. 'Undecidable' free forms – particularly free indirect ones – foreground uncertainties in readers' knowledge of characters and narrator. Consider the following extract, for example, which comes late in Lawrence's *Women in love*, when a womanservant confirms to Gudrun that her former lover, Gerald Crich, has, as suspected, perished in the Alpine cold. The final sentence seems largely to be the womanservant's FIT, but it may have something of the narrator's voice in it, and even something of Gudrun's own thoughts (as in the preceding Gudrun FIT); and is it not, in a sense, a fair comment on Gudrun?

> "Il est mort?"
> "Yes – hours ago."
> Gudrun did not know what to say. What should she say? What should she feel? What should she do? What did they expect of her? She was coldly at a loss.
> "Thank you," she said, and she shut the door of her room. The woman went away mortified. Not a word, not a tear – ha! Gudrun was cold, a cold woman. (Lawrence, *Women in love*, chap. 31)

A final remark is in order concerning the importance of forms of thought representation in modern literature, notwithstanding the degree of artifice or counterfactuality entailed in purporting to report the contents of another person's mind. For although new technologies and art forms have come along, diverting attention away from literature, the latter retains a particular special status as a forum for the exploration and dramatization of consciousness. It is then as much an opportunity as a difficulty that, by contrast with the establishment of DS as the normal way of relaying other's heard utterances, thoughts are represented in more various ways. Thought is such an amorphous entity, seemingly a cover term for a range of mental activities only some of which are remotely capturable with the linearity of language, that no single format of presentation has emerged as the standard. Many commentators would argue that there can be no such thing as 'thought transcription' truly on a par with 'speech transcription', and that at best thoughts can be described, not transcribed (just as body movements might be described but not transcribed). Another major distinction concerns genres of use: although speech representation is central to a host of human activities and institutions, thought representation has been largely confined (with exceptions in, e.g., biography and personalized journalism) to the realms of literary fiction. In fact thought representation is a distinguishing feature of modern literature and one of its chief assets; despite all the advances in neurological and cognitive science, perhaps no other cultural form is so powerful at appearing able to make available to us other peoples' minds, and the unlimited movements of consciousness. High in the roll call of great novelists who have given us, via thought representation, insights into the chaotic architecture of others' minds and the oceanic storms of emotion and desire that may rage therein are Dostoyevsky, Proust, Joyce, and Woolf. But the examined mental life has been a literary interest since the earliest times, and only became more entrenched, a preoccupation, in the modernist period, roughly contemporaneously with an explosion of interest in psychology and psychiatry ushered in by the work of William James, Freud, and Jung.

Discourse Categories as Superordinate to Speech and Thought Modes

So far in this article, the major categories of speech representation have been discussed separately from those of thought representation, and there are certainly good reasons for doing so. On the other hand, as has been clear in the foregoing, there are many similarities of form, and some of effect also, between the core speech categories DS, FIS, IS, and NRSA and counterpart core thought ones of DT, FIT, IT, and NRTA. Accordingly a useful practice has developed of replacing the terms *speech* and *thought* by a superordinate one, *discourse*, giving rise to a set of superordinate labels (especially DD, FID, and ID), and in the remainder of this article these portmanteau terms will sometimes be used. But it remains true that in the actual reading of a text one encounters not ID but something that is clearly either IS or IT (and only rarely – but interestingly – is assignment of an utterance to the 'S' or the 'T' scale undecidable). So in analysis the more precise labels are preferable.

Who Speaks, Who Thinks?

In the reading and analysis of literary (and other) narratives, it is often crucial to determine who is underlyingly responsible for the words – possibly implied to have been spoken, or simply thought – that one encounters. With regard to FIS and FIT, the question amounts to the following: 'To whom do we attribute these spoken words or articulated thoughts?' The 'Who is saying/thinking this?' question is useful to keep in mind, because FID is a very open category. Despite the foregoing list of usual indicators of FID, there is no single *necessary* feature of FID, which you have to have in order for a phrase or clause to qualify as FID. Narratives in the present tense (where there will be no tense difference between direct and indirect discourses) or with first-person narrators can just as easily contain FID as other types. As Leech and Short (1981: 328–33) show in the following two examples, a single character-attributed expletive, or even a single character-expressive punctuation mark, can in suitable context signal the presence of FID rather than narratorial indirect discourse:

> He said that the bloody train had been late.
> He told her to leave him alone!

We assume that the *bloody* is the character's (*He*), and not the narrator's, and similarly that at least the exclamation mark is the character's. These examples highlight another interesting uncertainty of FID examples: the lack of a decisive indication of the mode's extent. Thus in the first example, 'how much', before and after the word *bloody*, is also essentially attributable to the character? And in the second example, is the entire clause 'leave him alone!' FID, or only 'alone!', or merely the exclamation point?

Finally, how all-encompassing should FID and similar discourse-representing categories be conceived

to be? A traditional distinction (from Genette) has proposed separate answers to the questions 'Who speaks?' and 'Who sees?,' the former giving rise to the range of speech and thought presentation categories, the latter being addressed by specification of various kinds and degrees of focalization. But this division is by no means universally accepted among narratologists and stylisticians. It is so often the case that, for example, FIT goes hand in hand with focalization from the viewpoint of that character, that it seems that only in exceptional cases are the two noticeably distinct or held apart. Or some have wondered whether all cases of focalization as encoded or expressed in the text cannot be reinterpreted as kinds of FID. On the other hand those who argue that it is useful to address focalization choices separately from speech and thought presentation ones are also, in effect, arguing for a more delimited notion of ID and FID; they maintain that we should not include, under ID or FID, cases of narrative report that adopt or express only the character's spatio-temporal viewpoint, their orientation, without any of the character's (outer or inner) words.

Testing for FID

Two simple framing or commutation tests can be helpful in probing for the FID status or (or otherwise) of doubtful extracts. Those frames are (to support a PN – purely narratorial – or ID categorization):

> **I, the narrator, tell you, the reader** [insert text to be probed, unmodified]

and, alternatively (to support categorization as FID):

> [insert text to be probed, with any pronouns referring to the putatively discoursing character converted to first person, and with tenses converted to the present tense of thinking/speaking], **the character remarks, to themself or to other characters.**

Any sentence, or sentence part, can be put to these framing tests to help clarify their FID or PN status. But it has to be conceded that the shorter the fragment to be probed, the more difficult is this test to use; and FID does not invariably come in clause-size chunks. Still, to see how on longer fragments the test can be useful confirmation, consider these sentences from an early point in Gabriel's final revery in 'The Dead':

> Perhaps she had not told him all the story.(1) His eyes moved to the chair over which she had thrown some of her clothes. . ..(2) Poor Aunt Julia! She, too, would soon be a shade . . . (3)

Taking these slightly out of order, the second of these sentences is clearly narratorial: although it fits the narratorial frame quite unexceptionally, it is clearly ludicrous if explicitly cast as characterological, via the second frame:

> My eyes move to the chair over which she has thrown some of her clothes, the character remarks (to himself).

Conversely, sentence (3) is almost as incontestably characterological, FIT. Finally, the first sentence *Perhaps she had not told him all the story*, taken alone would seem to pass both the narratorial and characterological probe test: good evidence that, in theory, the sentence could be either narrator's suggestion or character's speculation. Again, context and cotext (and content: despite his rather protracted interrogation of her, it would be in Gabriel's character to fear or suspect that not even Gretta had been entirely honest with him) make it overwhelmingly more appropriate to read this potentially ambiguous observation as Gabriel's, in FIT.

As much as anything else, it is the modality in this last example – *Perhaps she had not told* etc. – and the expressive evaluation in the previous example – *Poor Aunt Julia! She, too*, etc. – that encourage us to assign FID interpretations. In seemingly narrative text, FID has the capacity to 'put back' all the immediacy and subjectivity and expressivity that otherwise, in standard ID, gets edited out. And this 'restored' subjective expressivity can extend to eccentricities of spelling and writing in general, reflecting the nonstandardness of the character: such features are comfortably accommodated in some kinds of FID. All of this amounts to a restoration of the colorful individuality of characters' direct expression. We feel FID to be more vivid and colorful than PN and ID report because both the latter tend to be more detached, sober, restrained, and standard-English-speaking than the words of the character *in situ*, undergoing the experience and talking and thinking their way through that experience in frank and uninhibited ways. Of course the latter is an *effect* of direct experiential reaction, but no less significant for that.

As elsewhere in narrative study, it is the perception of difference (here between character speech and narrator speech) that is the true criterion. And in some narratives, as in the novels and stories of Henry James, where narrator and characters seem to share a single lect so that contrasts scarcely arise at lexico-grammatical levels at all, the differences can only be painstakingly derived from a reader's assessment of protagonists and their discourse (e.g., its varying degrees of reasonableness).

FID: Functions and Effects

Perhaps no other feature of literary language has attracted as much attention from so broad a range

of critics and linguists in the last 100 years as FID. Some have especially emphasized the 'dual voice' effect of FIS: notably in the work of Ullman, Pascal (1977), and McHale (1978), as well as in various of Bakhtin's writings. Others, developing ideas in Benveniste and Hamburger, have dwelt on the 'unspeakability' of the FID sentence and of narrative sentences generally (especially Banfield, 1982). For Banfield, narration is unspeakable because, unlike discourse (which is both communicative and expressive), it is a text with neither a genuine addressee (nor any textual traces of one) nor a genuine expressivity-disclosing speaker. FID, in partial contrast, carries abundant expressivity (that of the character), but still no genuine I-you communicativity, and as a result remains unspeakable. Depending upon how the object of study – the novel, for example – is viewed, both or all of these seemingly disparate claims are defensible and insightful. And it certainly seems likely that the 'disappearance' of the teller from heterodiegetic narratives, the bleaching out of the narrator as a felt presence in the text and denoted by prominent use of the first person singular pronoun and by evidentials, may have created the conditions in which free indirect effects could first emerge.

FID can be related to such fundamental literary distinctions of narrative method as those between showing and telling, or the neo-Platonist terms *mimesis* and *diegesis*. Mimesis presents 'everything that happened' as this might be perceived by a witness within the scene (thus a partial and far from comprehensive account). Stanzel (1981) noted that it typically comes with internal character focalization. Diegesis presents everything that a detached external reporter decides is worth telling – a reporter who is able to reflect, reorganize, and decide upon the point or teleology of the story prior to narrating it. In terms of mimesis and diegesis, FID amounts to a mimetic diegesis (a telling that shows or presents aspects of the character's 'own' words or thoughts). In particular it is a showing that does not, by comparison with DD forms, draw so much attention to itself or to the fact that it is a showing. As a device for character portrayal by covert showing, FID can be related to a more thoroughgoing narrative strategy for showing character, known as Mind Style, in which the whole style of a passage or section seems to reflect the quality of someone's mind – usually the mind of a focalizing character (*see* **Mind Style**).

But there are numerous ways of characterizing FID, in fact, and these varied characterizations reflect the various functions that, in different circumstances, it can serve. It has been called substitutionary narration; combined discourse; 'contaminated' narrative, a tainting or coloring of the narrative; and dual voicing. Yet another approach is to view FID as a strategy of (usually temporary or discontinuous) alignment, in words, values, and perspective, of the narrator with a character. The idea of alignment does not prescribe whether that closeness of narrator to character is used for purposes of irony, empathy, as a vehicle for stream-of-consciousness or the clashing of two voices, or some other purpose.

Like McHale and others (Pascal, 1977; Ginsberg, 1982), Jefferson recognized that a key source of the impact of the FID sentence is its ambiguous mixture of proper narrative and proper speech or thought:

> The dual voice of FID which is responsible for the superficially realist effect of immediacy is also an ambiguity which is highly unrealistic. From a realist point of view, FID is a doubly disconcerting use of language: its ambiguities cut it adrift from the two points at which we commonly imagine language to be anchored to reality, the speaker and the referent. It is neither fully expressive nor fully referential, and this *invraisemblance* differentiates it most profoundly from other forms of reported discourse. (Jefferson, 1981: 42)

By *invraisemblance* Jefferson alludes in part to FID's lack of *vraisemblance*: the effect or convention of faithful and 'realistic' representation of the real world that many novels foster and many readers demand. The *invraisemblance* of FID stems from the fact that it gives rise to sentences such as *Perhaps she had not told him all the story*, and *She too would soon be a shade* and *Yes, the newspapers were right* which, in just those forms and with just those referential commitments, none of us in the discoursing of everyday lives, including our storytellings embedded in conversations, could ever actually say. FID sentences are in this sense unsayable or unspeakable, impossible to anchor to one speaker at one place and time, because they are impossibly divided between two distinct speakers (narrator and character) and anchorages. Following Bakhtin/Voloshinov, critics have argued that in some of these cases the represented speech or thought is 'reaccented' by the representing narrator, so that two distinct accents, dialects, or intonations (which are never neutral, always evaluative) are held in a rich, unresolved tension. Certainly on some occasions, the clash of (character's and narrator's) sentiments within the FID passages is so palpable that a kind of internal conflict or mutual contradiction seems to be enacted.

Carefully handled FIT rendering can contribute to a subtle narrative presentation of characters' thoughts,

in which the reader's awareness that a narrator is relaying those thoughts (even though narrator-oriented tense and pronoun choices are made) is thoroughly backgrounded. No matter how audacious or unreasonable the character's views become, no narratorial voice of 'true judgment' intrudes to censure the character or to dissociate itself from the character and *alert* the reader to the errors being broadcast. But actually FIT is often most powerful where the articulated ideas are *not* glaringly at odds with the narrator's assumed stance. Rather than by insulting or at least ignoring the reader's intelligence by imposing a narratorial gloss on the character's thoughts (there is no guarantee that the narrator is wiser, fairer, and more consistent than the characters, but that is the usual expectation), narration involving copious FIT – particularly when, as noted earlier, there is little reliably or blatantly to distinguish what the narrator might have reported in their own voice from what the character may have privately thought – may challenge the reader's intelligence and moral sensibility or discernment. And in exercising that discernment we may have help only from juxtaposition: e.g., of one character's self-serving evaluations with actual outcomes or other characters' actions. Such effects are continually achieved in the novels of Henry James.

Finally, another indicator of the exceptionality of FID is the way that it often presents particular challenges to the translator. Translation of FIS and FIT passages creates all kinds of challenges – e.g., when expressing what might be rendered in English as *How she loathed him!* in a language such as Finnish, which has only one gender-neutral third-person singular personal pronoun, *hän*. Or it may be that the prohibitions on introduction of character-expressive features into a sentence with ID tense and deictic selections may be rather stricter in the target language than in the source language (or vice versa) creating further incommensurabilities.

'Beyond' IT: NRTA and NI

The work of Leech and Short (1981), and very recently Semino and Short (2004), has done much to develop a systematic typology of speech and thought (and latterly, writing) representation categories relevant to English. Most of the categories they propose are widely adopted, but the two 'most indirect' ones for thought representation, merit further comment (the counterpart ones for speech, NRSA and NV, were discussed earlier). They are NRTA and NI. NRTA denotes narrative report of thought acts, and is roughly parallel to Cohn's category of psychonarration, in which the heterodiegetic narrator remains in the foreground throughout, even adds some general observations not originating in the character ("as others [...] had done before him"). In NRTA, then, there is a highly indirect report of a character's or characters' thought, in which the content is noticeably summarized and cast in narratorial terms. Very often an NRTA sentence serves to introduce a passage of more character-expressive discourse. In the following example, an NRTA sentence (here in bold) is flanked by FIT ones:

> She had consented to go away, to leave her home. Was that wise? **She tried to weigh each side of the question**. In her home anyway she had shelter and food; she had those whom she had known all her life about her. O course she had to work hard, both in the house and at business. (Joyce, 'Eveline', *Dubliners*)

The new internal narration (NI) category has been proposed for "reports of mental states and changes that involve cognitive and affective phenomena but that do not to amount to specific thoughts" (Semino and Short, 2004: 132), that is, reports of mental activity that is even less a matter of inner speech than NRTA instances. The examples include the following (which all need to be imagined in appropriate contexts):

> *Jim envied Mr Mulvaney;*
> *The phrase made me a little sad;*
> *I couldn't get the image out of my head.*

That there is narrational activity of this kind, where a character's affective or evaluative response is conveyed in nonspecific terms, is widely accepted. But whether this amounts to *thought*-presentation, where 'thought' denotes 'the reported words or wording that we treat as having run through the character's or narrator's head', is more open to question. It is not claimed or assumed that the actual words *envy* or *sad* or *can't get the image* registered on the consciousness of the individuals here reported experiencing these emotions or reactions, any more than if the text reported *Jim pummeled Mr Mulvaney* it would imply that the word *pummel* crossed Jim's consciousness. For that reason, some analysts prefer to categorize such examples on the other side of a watershed setting apart thought representation from narration, i.e., on the narration side. These examples are then treated as more about narration, mental response narration perhaps, than thought presentation – as indeed the NI labeling partly recognizes. They are judged not to sit comfortably within the same grouping as DT, FIT, and IT (where NRTA is regarded as

the outlier or 'most indirect' category). Whatever classification is adopted, the recent study of Semino and Short suggests that NI-type narrations of mental reactions are by some way the most frequent means of thought presentation (presentation, not representation, is significantly their preferred term) in modern fiction, biography, and journalism. They therefore merit further analyses and appropriate classification on a comprehensive narrational scale that might encompass the whole range from discourse representation, through narrative report, description, and comment (Bonheim, 1984).

Conclusion

As a topic in narratology and literary linguistic analysis, speech and thought representation will continue to dwell on the different ways and effects of rendering direct speech in fiction and on the subtly changing ways that writers are finding to create mergers, blends, alignments, and clashes of voices and viewpoints within FID. The point is worth emphasizing that all six main speech and thought representation types (DS, IS, FIS; DT, IT, FIT) are effects as much as they are stable formats defined by essential criteria (DS is in the present tense of actual speech, but so too can narration be; it may or may not have quotation marks, be set out on the printed page on a new line, with indentation, at each change of speaker, and so on). And in various ways just what is 'licensed' or acceptable in each of these mutually defined formats changes in step with larger changes in the status and function of literature, with changes of technology and living conditions, and especially in the face of the rivalry from alternative (and themselves changing) modes of cultural production and consumption, such as film, theater, and television. In short what is grammatical in each of these formats has shifted over time, and to some degree will continue to, and such shifts are both a cause and an effect of readers' changing literacy skills in this area – their adjusted ability to read and accept such a format as an effective rendering of a character's articulated thoughts, or of such thoughts interwoven with a narrator's distinct (and variably sympathetic or critical) viewpoint.

Introduction

Speaking and listening is so fundamental that people take it for granted. Every day, people ask questions. They give instructions. Speaking and listening are necessary for learning and training, for selling and buying, for persuading and agreeing, and for most social interactions. For the majority of people, speaking and understanding spoken speech is simply the most convenient and natural way of interacting with other people.

So, is it possible to speak and listen to a computer? Yes.

Emerging technology now enables users to speak and listen to the computer. Speech recognition converts spoken words and phrases into text, and speech synthesis converts text to human-like spoken words and phrases. While speech recognition and synthesis have long been in the research stage, three recent advances have enabled speech recognition and synthesis technologies to be used in real products and services: (1) faster, more powerful computer technology; (2) improved algorithms using speech data captured from the real world; and (3) improved strategies for using speech recognition and speech synthesis in conversational dialogues, enabling users to speak and listen to the computer.

Motivation for Speaking and Listening to a Computer

Speech applications enable users to speak and listen to a computer . . .

- despite physical impairments such as blindness or poor physical dexterity. Speaking enables physically impaired callers to access computers. Callers with poor physical dexterity (who cannot type) can use speech to enter requests to the computer. The sight-impaired can listen to the computer as it speaks. When visual and/or mechanical interfaces are not an option, callers can perform transactions by saying what they want done and supplying the appropriate information. If a person with impairments can speak and listen, that person can use a computer.
- to bypass the limitations of small keyboards and screens. As devices become smaller, our fingers do not. Keys on the keypad shrink – often to the point where people with thick fingers press two or more keys with one finger stroke. The small screens on some cell phones may be difficult to see, especially in extreme lighting conditions. Even PDAs with QWERTY keyboards are awkward. (*QWERTY* is a sequence of six keys found on traditional keyboards used by most English and Western European language speakers.) Users hold the device with one hand and 'hunt and peck' with the forefinger of the other hand. It is impossible to use both hands to touch-type while also holding the device. By speaking, callers can bypass the keypad (except possibly for entering private data in crowded or noisy environments). By speaking and listening, callers can bypass the small screen of many handheld electronic devices.
- if the device has no keyboard. Many devices have no keypad or keyboard. For example, stoves, refrigerators, and heating and air conditioning thermostats have no keyboards. These appliances may have a small control panel with a couple of buttons and a dial. The physical controls are good for turning the appliance on and off and adjusting its temperature and time. Without speech, a user cannot specify complex instructions such as 'Turn the temperature in the oven to 350 degrees for 30 minutes, then change the temperature to 250 degrees for 15 minutes, and finally leave the oven on warm.' Without speech, the appliance cannot ask questions such as, 'When on Saturday morning do you turn the heat on?' Any sophisticated dialogue with these appliances will require speech input. And speech can be used with rotary phones, which do not have a keypad.
- while callers work with their hands and eyes. Speaking and listening are especially useful in situations where the caller's eyes and/or hands are busy. Drivers need to keep their eyes on the road and their hands on the steering wheel. If they must use a computer when driving, the interface should be speech only. When driving machines that require their hands to operate controls and their eyes to focus on the machine activities, machine operators can also use speech to communicate with a computer (although it is not recommended that you hold and use a cell phone while driving a car). Parents and caregivers with children in their arms may also appreciate speaking and listening to a doctor's web page or medical service. If a person can speak and listen to others while they work, they can speak and listen to a computer while they work.
- at any time during the day. Many telephone help lines and receptionists are available only during

working hours. Computers can automate much of this activity, such as accepting messages, providing information, and answering callers' questions. Callers can access these automated services 24 hours a day, 7 days a week via a telephone by speaking and listening to a computer. If a person can speak and listen, they can interact with a computer any time during the day or night.

- with instant connection without being placed on 'hold.' Callers become frustrated when they hear 'your call is very important to us' because this message means they must wait. 'Thanks for waiting, all of our operators are busy' means more waiting. When using speech to interact with an application, there are no hold times. The computer responds quickly. (However, computers can become saturated, which results in delays; but these occur less frequently than with callers waiting for a human operator.) Because many callers can be serviced by voice-enabled applications, the human operators are freed to resolve more difficult caller problems.
- using languages that do not lend themselves to keyboarding. Some languages do not lend themselves to data entry using the traditional QWERTY keyboard. Rather than force Asian language users to mentally translate their words and phrases to phonetic sounds and then press the corresponding keys on the QWERTY keyboard, a much better solution is to speak and listen. Speech and handwriting recognition will be the key to enabling Asian language speakers to gain full use of computers. If a person can speak and listen to an Asian language, they can interact with a computer using that language.
- to convey emotion. In an effort to enhance written text in order to convey emotions, callers frequently use 'emoticons' – keyboard symbols to convey emotions – to enhance their text messages. Example emoticons include :) for happy or a joke and :(for sad. With speech, these emotions can be conveyed naturally by changing the inflection, speed, and volume of the speaking voice.
- to use multiple channels of communication between user and computer. Speech enhances traditional GUI user interfaces by enabling users to speak as well as click and type, and hear as well as read. Multimodal user interfaces will improve the exchange of information between users and computers by transferring information in the most appropriate mode – speech for simple requests and simple answers, and GUIs for complex requests and graphical and pictorial answers.

Languages for Speech Applications

This new environment led to the creation of VoiceXML, an XML-based declarative language for describing the exchange of spoken information between users and computers and related languages. The related languages include the Speech Recognition Grammar Specification (SRGS) for describing what words and phrases the computer should listen for and the Speech Synthesis Markup Language (SSML) for describing how text should be rendered as verbal speech. VoiceXML is widely used to develop voice-only user interfaces for telephone and cell phone users.

VoiceXML uses predefined control structures, enabling developers to specify what should be spoken and heard, but not the low-level details of how those operations occur. As is the case with many special-purpose declarative languages, developers sometimes prefer to write their own procedural instructions. Speech Application Language Tags (SALT) was developed to enable web developers to use traditional web development languages to specify the control and use a small number of XML elements for managing speech. In addition to telephony applications, SALT can be used for multimodal applications where people use multiple modes of input – speaking, as well as typing and selecting (pointing).

SALT

The SALT Forum, originally consisting of Cisco, Comverse, Intel, Microsoft, Philips, and SpeechWorks (now Nuance), published the initial specification in June 2002. This specification was contributed to the World Wide Web Consortium (W3C) in August of that year. In June 2003, the SALT Forum contributed a SALT profile for Scalar Vector Graphics (SVG) to the W3C.

The SALT specification contains a small number of XML elements enabling speech output to the user, called prompts, and speech input from the user, called responses. SALT elements include:

- *<prompt>* – presents audio recordings and synthesized speech to the user. SALT also contains a prompt queue and commands for managing the presentation of prompts in the queue to the user
- *<listen>* – recognizes spoken words and phrases. There are three listen modes:
  - *Automatic* – used for recognition in telephony or hands-free scenarios. The speech platform, rather than the application, controls when to stop the recognition facility.

- *Single* – used for push-to-talk applications. An explicit stop from the application returns the recognition result.
- *Multiple* – used for 'open-microphone' or dictation applications. Recognition results are returned at intervals until the application makes an explicit stop.

- *<grammar>* – specifies the words and phrases a user might speak
- *<dtmf>* – recognizes DTMF (telephone touch-tones)
- *<record>* – captures spoken speech, music, and other sounds
- *<bind>* – integrates recognized words and phrases with application logic
- *<smex>* – communicates with other platform components

SALT designers subsetted the SALT functionality into multiple profiles that are implemented and used independently of the remaining SALT modules. Various devices may use different combinations of profiles. Devices with limited processor power or memory need not support all features (for example, mobile devices do not need to support dictation). Devices may be tailored to particular environments (for example, telephony support may not be necessary for television set-top boxes). While full application portability is possible within devices using the same profile, there is limited portability across devices with different profiles.

SALT has no control elements, such as *<for>* or *<goto>*, so developers embed SALT elements into other languages, called host languages. For example, SALT elements may be embedded into languages such XHTML, SVG, and JavaScript. Developers use the host language to specify application functions and execution control, while the SALT elements provide advanced input and output using speech recognition and speech synthesis.

Architectures for SALT Applications

Users interact with telephony applications using a telephone, cell phone, or other mobile device with a microphone and speaker. The hardware architecture for telephony applications, illustrated in Figure 1, contains:

- *Web server* – contains HTML, SALT and embedded scripts. The scripts control the dialogue flow, such as the order for playing audio prompts to the caller.
- *Telephony server* – connects the IP network (and the speech server) to the telephone network.

Figure 1 Hardware architecture for telephony applications.

- *Speech server* – contains a speech recognition engine that converts spoken speech into text, a speech synthesis engine that converts text to human-sounding speech, and an audio subsystem for playing prompts and responses back to the user.
- *Client devices* – device to which the user listens and speaks, such as mobile telephones and telephony-enabled PDAs.

There are numerous variations for the architecture shown in Figure 1. A small speech recognition engine could reside in the user device (for example, to recognize a small number of command and control instructions), or it may be distributed across the device and speech server (the device performs DSP functions on spoken speech, extracting 'speech features' that are transmitted to the speech server that concludes the speech recognition processing). The various servers may be combined or replicated, depending upon the workload. And the telephony server could be replaced by Internet connections to speech-enabled desktop devices, bypassing the telephone communication system entirely.

Some mobile devices – and most desktop devices – have screens and input devices such as keyboard, mouse, and stylus. These devices support multimodal applications, which support more than one mode of input from the user, including keyed text, handwriting and pen gestures, and spoken speech.

Telephony and Multimodal Applications Using SALT

Figure 2 illustrates a sample telephony application written with SALT elements embedded in HTML. The bolded code in Figure 2 will be replaced by the

Figure 3 Multimodal application written using SALT tags. The bolded code in Figure 3 replaces the bolded code in Figure 2.

bolded code in Figure 3, which illustrates the same application as a multimodal application.

Figure 3 illustrates a typical multimodal application written with SALT and embedded in HTML. In this application, the user may either speak or type to enter values into the text boxes. Note that the code in Figure 3 is somewhat different from the code in Figure 2. This is because many telephony applications are system-directed (the system guides the user by asking questions that the user answers), while, as

with visual-only applications, multimodal applications are often user-directed (the user indicates which data will be entered by clicking a mouse or pointing with a stylus and then entering the data).

Programming with SALT is different from programming traditional visual applications in the following ways:

- If the developer does not like how the speech synthesizer renders text as human-understandable voice, the developer may add Speech Synthesis Markup language (SSML) elements to the text to provide hints for the speech synthesis system. For example, the user could insert a <break time = "500ms"/> element to instruct the speech synthesizer to remain silent for 500 milliseconds. SSML is a W3C standard and is used by both SALT and VoiceXML 2.0/2.1.
- The developer must supply a grammar to describe the words and phrases users are likely to speak. Grammars help the speech recognition system recognize words faster and more accurately. SALT (and VoiceXML 2.0/2.1) developers specify grammars using the Speech Recognition Grammar Specification (SRGS), another W3C standard. An example grammar is illustrated in Figure 2, lines 44–54. Application developers should spend effort in fine-tuning the specification of grammars to recognize words frequently spoken by the user at each point in the dialogue, as well as fine-tuning the wording of the prompts to encourage users to speak those words and phrases.
- Speech recognition systems do not understand spoken speech perfectly. (Even humans occasionally misunderstand what others say.) In the best circumstances, speech recognition engines fail to accurately recognize 3 to 5% of spoken words. Developers compensate for poor speech recognition by writing event handlers to assist users in overcoming speech recognition problems. They prompt the user to speak again, often rephrasing the question differently so the user responds by saying different words. Example event handlers are illustrated in Figure 2, lines 35–37 and lines 38–40. Developers may spend as much as 30 to 40% of their time writing event handlers that are needed occasionally but are essential when the speech recognition system fails.

Comparison of SALT with VoiceXML

SALT and VoiceXML enable very different approaches for developing speech applications. SALT tags control the speech medium (speech synthesis, speech recognition, audio capture, audio replay, and DTMF recognition). SALT tags are often embedded into another language that specifies flow control and turn-taking. On the other hand, VoiceXML is a standalone language that controls the speech medium as well as flow control and turn-taking.

In VoiceXML, the details of flow control are managed by an a special algorithm called the Forms Interpretation Algorithm. For this reason, many developers consider VoiceXML a 'declarative' language. On the other hand, SALT is frequently embedded into a procedural programming language. Many developers consider the programming languages into which SALT is embedded to be 'procedural.' It should be noted, however, that SALT can be used as a standalone declarative language by using the assignment and conditional features of the <bind> statement. Thus, SALT can be used in resource-scarce platforms such as cell phones that cannot support a host language. For details, see section 2.6.1.3 in the SALT specification.

While SALT and VoiceXML make it easy to implement speech-enabled applications, it is difficult to design a quality speech application. A HTML programmer easily learns how to write SALT applications, but designing a usable speech or multimodal application is still more of an art than a science. Balentine and Morgan (2004) and Cohen *et al.* (2004) present guidelines and heuristics for designing effective speech dialogues. A series of iterative designs and usability tests are necessary to implement speech applications for users to both enjoy and use efficiently to perform their desired computer tasks.

Conclusion

It is not clear when this article was written if SALT will overtake and replace VoiceXML as the most widely used language for writing telephony applications. It is also not clear if SALT or some other language will become the preferred language for developing multimodal applications. The availability of high-level design tools, code generators, and system development environments that hide the choice of development language from the speech application developer may minimize the importance of programming language choice.

Speech Community

M Scherre, University of Brasília, Brasília, Brazil

© 2006 Elsevier Ltd. All rights reserved.

Independently of theoretical orientation, the goal of scholars in attempting to formulate the conceptual foundations of the notion of speech community is to capture the forces that interact in the natural process of language-based group formation. In this connection, language is viewed as an intricately structured multifunctional system acting within the domains of communication, organization of thought, social interaction, group identification, symbolic integration, and even discrimination and social exclusion of the powerless. Three components can be discerned in the three principal lines of thought found in the relevant literature. First, as a necessary condition for a speech community, the existence of shared linguistic systems or abstract structural patterns is universally assumed. The existence of social norms of use and interpretation, on the one hand, and of a set of social attitudes towards language, on the other hand, are both complementary conditions, each of which can be emphasized in different ways. These three components, depending on the analyst's point of view, determine the perceived size of a speech community, increasing or decreasing the number of participants included in it. Each scholar captures part of the complex reality of real-world speech communities in a unique way.

Reflecting different views of the relationship between language and society, formulations of the concept of the speech community have evolved together with the development of language sciences. These characterizations take account of and intersect linguistic, geographical, ethnic, and social boundaries.

Summary of Concepts of Speech Community

The principal conceptual views of the speech community are associated with three paradigms of language studies: Structural Linguistics; Sociology of Language and Ethnography of Communication; Labovian Sociolinguistics. Bloomfield (1961/1933), Hockett (1958), and Lyons (1973/1970) are the leaders of the first line of definitions; Gumperz (2001/1962, 1972/1968), Fishman (1971), and Hymes (1972/1967, 1981/1974) lead the second thread; the third strand is due to Labov (1989, 1975/1972). Because these three groups represent different theoretical paradigms, it is inevitable that their views of the speech community are, at the same time, conflicting and complementary: they deal with articulated language and organization of society, two features that distinguish humans from other animals. But, each type of definition brings into focus different aspects of human language on the formal, political, social, interactional, and symbolic integration planes, reflecting the authors' perspectives on the relationship between language and society. Some viewpoints emphasize formal or political configurations, while others highlight social or interactional circumstances, and still others attempt to achieve equilibrium between social and formal aspects.

Definition of Speech Community in Structural Linguistics

The underlying characteristic common to definitions of the speech community within the framework of Structural Linguistics is **the existence of the same language within the community.** According to Bloomfield (1961: 29), "a group of people who use **the same system** of speech-signals is a *speech-community*"; for Hockett (1958: 8), "each language defines a *speech community*: the whole set of people who communicate with each other, directly and indirectly, via the **common language**"; for Lyons (1973: 326), "*speech community* [is] all the people who use **a given language (or dialect)**."

In line with the linguistic school they represent, **classical structuralism**, with its emphasis on the

Independently of theoretical orientation, the goal of scholars in attempting to formulate the conceptual foundations of the notion of speech community is to capture the forces that interact in the natural process of language-based group formation. In this connection, language is viewed as an intricately structured multifunctional system acting within the domains of communication, organization of thought, social interaction, group identification, symbolic integration, and even discrimination and social exclusion of the powerless. Three components can be discerned in the three principal lines of thought found in the relevant literature. First, as a necessary condition for a speech community, the existence of shared linguistic systems or abstract structural patterns is universally assumed. The existence of social norms of use and interpretation, on the one hand, and of a set of social attitudes towards language, on the other hand, are both complementary conditions, each of which can be emphasized in different ways. These three components, depending on the analyst's point of view, determine the perceived size of a speech community, increasing or decreasing the number of participants included in it. Each scholar captures part of the complex reality of real-world speech communities in a unique way.

Reflecting different views of the relationship between language and society, formulations of the concept of the speech community have evolved together with the development of language sciences. These characterizations take account of and intersect linguistic, geographical, ethnic, and social boundaries.

Summary of Concepts of Speech Community

The principal conceptual views of the speech community are associated with three paradigms of language studies: Structural Linguistics; Sociology of Language and Ethnography of Communication; Labovian Sociolinguistics. Bloomfield (1961/1933), Hockett (1958), and Lyons (1973/1970) are the leaders of the first line of definitions; Gumperz (2001/1962, 1972/1968), Fishman (1971), and Hymes (1972/1967, 1981/1974) lead the second thread; the third strand is due to Labov (1989, 1975/1972). Because these three groups represent different theoretical paradigms, it is inevitable that their views of the speech community are, at the same time, conflicting and complementary: they deal with articulated language and organization of society, two features that distinguish humans from other animals. But, each type of definition brings into focus different aspects of human language on the formal, political, social, interactional, and symbolic integration planes, reflecting the authors' perspectives on the relationship between language and society. Some viewpoints emphasize formal or political configurations, while others highlight social or interactional circumstances, and still others attempt to achieve equilibrium between social and formal aspects.

Definition of Speech Community in Structural Linguistics

The underlying characteristic common to definitions of the speech community within the framework of Structural Linguistics is **the existence of the same language within the community.** According to Bloomfield (1961: 29), "a group of people who use **the same system** of speech-signals is a *speech-community*"; for Hockett (1958: 8), "each language defines a *speech community*: the whole set of people who communicate with each other, directly and indirectly, via the **common language**"; for Lyons (1973: 326), "s*peech community* [is] all the people who use **a given language (or dialect)**."

In line with the linguistic school they represent, **classical structuralism**, with its emphasis on the

study of internal structure, these scholars take into account, on the one hand, language as a formal mechanism, that is, the abstract structure underlying utterances (Lyons, 1973: 15); and, on the other hand, language as a political mechanism, functioning through the politically and culturally important abstract system known as standard language (Lyons, 1973: 19). Bloomfield (1961: 42) admits social factors into the definition of speech community by mentioning interaction when he states: "a speech-community is a group of **people who interact by means of speech** (...), therefore, is **the most important kind of social group**." Nonetheless, Bloomfield's definition (1961: 52) stresses the existence of a single language from the formal and political points of view, but not in its communicative function. He states: "our survey of differences within a speech-community has shown us that the members of a speech-community may speak so much alike that anyone can understand anyone else, or may differ so much that persons who live some distance apart may fail to understand each other." Furthermore, he goes on to note: "we speak of French and Italian, of Swedish and Norwegian, of Polish and Bohemian as separate languages, because these communities are politically separate and use different standard languages, but the differences of local speech-forms at the border are in these cases relatively slight" (Bloomfield, 1961: 54). Hockett (1958: 8) recognizes that "the boundaries between speech communities are not sharp," but nonetheless affirms that "most polyglots belong primarily to one speech community, and have only partial control of any other language, but there are occasional exceptions." He also states that (Hockett, 1958: 8) "in many cases the boundaries of a speech community coincide with political boundaries," although, according to him, different sorts of situations can be found: on the one hand, "Switzerland, a single political unit, includes speakers of four different languages: French, German, Italian, and Ladin (or Rhaetho-Romance)"; on the other hand, "English, as single language, is spoken not only in Britain (...)" but also in the United States. Furthermore, Hockett (1958: 9–10) also notes that when there are linguistic changes due to immigration or invasion, both of which may lead to new speech-habits and to misunderstanding, "we must then say that each subcommunity has become an independent speech community with **its own language**." This shows once again that the existence of a single language – in the formal and/or political sense of the term – is fundamental to the definition of speech community from the point of view of Structural Linguistics.

Definition of Speech Community in Sociology of Language and Ethnography of Communication

Gumperz, Hymes, and Fishman, departing from the structural approach, consider that the presence of more than one language does not necessarily imply the existence of more than one speech community. In the first definition of this group, Gumperz states that "a basic definitional property of speech communities is that they are *not* defined as communities of those who 'speak the same language' ... but, rather, **as communities set off by density of communication or/and by symbolic integration** (...) ***regardless of the number of languages or varieties employed***" (Fishman, 1971: 234). Gumperz, Hymes, and Fishman assume that the existence of at least one shared linguistic system is a necessary, but not a sufficient, condition for the characterization of a speech community and introduce a new feature common in subsequent definitions, namely, **shared knowledge of norms of use and interpretation of language**.

For Gumperz (2001: 43, 44, 1972: 463), a speech community is "any [monolingual or multilingual] human aggregate characterized **by regular and frequent interaction by means of a shared body of verbal signs**." (...) "Regardless of the linguistic differences among them, the speech varieties employed within a speech community form a system because they are related to **a shared set of social norms**." For Hymes (1981: 51), "a speech community is defined (...) as a community **sharing knowledge of rules for the conduct and interpretation of speech**. Such sharing comprises **knowledge of at least one form of speech, and knowledge also of its patterns of use. Both conditions are necessary**." For Fishman (1971: 232), "a speech community is one, all of whose members share **at least a single speech variety and the norms for its appropriate use**."

The definitions proposed by these three scholars are consistent with their theoretical approach, taking social norms for language use as their primary focus. According to Hymes (1972: 53-54), "speech is (...) taken as a surrogate for all forms of language, including writing, song and speech-derived whistling, drumming, horn calling, and the like. Speech community is a necessary, primary term in that it postulates **the basis of description as a social, rather than a linguistic, entity**." Social norms for language use and interpretation require communicative competence, reaching beyond knowledge of the abstract grammatical structures underlying speech acts to knowledge of social and linguistic rules of interaction including, for example, how and when to ask questions, to

whom younger speakers may put questions, which questions require an answer and which are merely rhetorical, whether another question can be superposed on the interlocutor's utterance, etc. The emphasis on the communicative and interactional aspects of language can be seen once more in the following words of Hymes (1972: 54): "the sharing of grammatical (variety) rules is not sufficient. There may be persons whose English I can grammatically identify but whose messages escape me. I may be ignorant of what counts as a coherent sequence, request, statement requiring an answer, requisite or forbidden topic (. . .), etc."

Definition of Speech Community in Labovian Sociolinguistics

Labov's (1989: 2, 1975: 120–121, 248) definition of speech community includes two features involved in previous attempts, but he widens their scope and, as a result, changes the focus. To the shared social norms of language use, Labov (1975: 248) adds "a set of social **attitudes** towards language." To the notion of linguistic system he adds the concept of abstract patterns of variation reflecting **orderly heterogeneity**. For Labov (1975: 120-121), "the speech community is not defined by any marked agreement in the use of language elements, so much as by participation in a set of shared norms; **these norms may be observed in overt types of evaluative behavior, and by the uniformity of abstract patterns of variation** (. . .)."

As we have seen in previous suggested characterizations, the definition of speech community given by Labov is consistent with the author's theoretical orientation, namely, Sociolinguistics or, more specifically, Quantitative Microsociolinguistics, Labovian Sociolinguistics, or Theory of Language Change and Variation. This approach has had great impact on sociolinguistic studies, especially in Brazil (Matos *et al.*), the United States, and Canada. Labov (1975: 184) states, "if there were no need to contrast this work with the study of language out of its social context, I would prefer to say that this was simply *linguistics*." The focus of Labovian Sociolinguistics is on language as an inherently variable system, the relationship between variation and change, and the effect of norms of social evaluation on language change. In a nutshell, it is an attempt to construct a theory of language change, characterized by Labov (1994: 5) as "a set of propositions that relate general findings about language change to general properties of human beings or of human societies." According to Labov (1994: 5), "to explain a finding about linguistic change will mean to find its causes in a domain outside of linguistics: in physiology, acoustic phonetics, **social relations**, perceptual or cognitive capacities." Furthermore, for Labov (2001: 514), the "Golden Age Principle," expressed as "*at some time in the past, language was in a state of perfection*," makes clear the existence of a uniform social attitude with respect to language, in turn revealing constant linguistic change within speech communities. Social features, in the sense of "**patterns of social stratification, style shifting, and subjective evaluations**" (Labov, 1989: 2), are, therefore, of fundamental importance in the Labovian approach, given that they are one of the elements external to linguistic structure that help to comprehend the mechanisms of variation and change that have an important role "in the makeup of the speech community" (Labov, 2001: 515).

Feelings, Dimensions, and Types of Speech Communities

The feeling of belonging to one or another speech community depends on the speaker's viewpoint, and language scholars have tried to capture and understand this feeling. For example, people from Brazil – a huge South American territory colonized by Portugal from 1500 to 1822 – may feel that they belong to the Brazilian speech community when they seek to highlight their unique identity with respect to the European Portuguese speech community, their main linguistic ancestor. Shared social norms of language use and interpretation play a role here, because those in Brazilian speech community are partially different from those in other Portuguese language speech communities, especially European Portuguese.

A good example of different social norms is the use of the pronoun *você* 'you (sg)'. This peculiar cross between a personal pronoun and a term of address is found in both communities, but the social norms associated with it are different in the spoken and written varieties of the language in the two countries. Within the set of forms with second person reference, in Portugal *você* 'you (sg)' is used in the asymmetric situation of a speaker with higher social status addressing a person of lower status. In Brazil, however, *você* 'you (sg)' is used among speakers of the same status in the Southeastern and Midwestern regions, and in more formal or less reciprocal interaction in the Southern and Northeastern regions, **but it does not mark an asymmetrical relationship of superior to inferior.** In written Brazilian Portuguese, *você* 'you (sg)' is the most frequent. It is often found, for example, in bank advertisements, an improbable context in Portugal, where zero would be preferred to refer to the reader. As far as the linguistic system is concerned, the lexical item *você* 'you (sg)' is part of the common

Portuguese language, but from the point of view of usage norms, this item separates Brazil and Portugal into two different communities. The difference is so salient that it can cause difficulties in dialogue between speakers from the two nations, and Brazilians often find bank advertising, and even posted signs, in Portugal to be very strange. In spoken personal interaction, European Portuguese speakers regularly use the name of the addressee as a form of reference to the second person, while many Brazilians would use *você* 'you (sg)'. To Brazilians, this Portuguese usage seems anomalous or reminiscent of baby talk and can even cause lack of comprehension when first heard. In Brazil, it is only used between parents and small children, especially in scolding. Facts such as these illustrate the position of Gumperz, Hymes, and Fishman, who all affirm that mere knowledge of grammar is a necessary, but not a sufficient, condition for the characterization of the notion of speech community.

Observing matters from another angle, Brazilians arriving in Portugal from, say, Germany, would feel that they are part of the wider Portuguese linguistic speech community currently consisting of Portugal, Brazil, Angola, Mozambique, São Tomé e Príncipe, Cape Verde Islands, Guinea-Bissau, Eastern Timor, and Macao. One of the features that unifies this macro community is the existence of Portuguese as an official language. This feeling of community crosses geographic borders, and does not take into account the existence of social norms of language use or evaluation. It is based essentially on the **symbolic integration** function of Portuguese as an official language. The feeling of speech community unity is also a result of the mutual intelligibility of technical and scientific written language and on the partial mutual comprehensibility that can be achieved in face-to-face interaction despite the undeniable structural and pragmatic differences. Even Gumperz (1972: 463), whose definition of speech community includes "regular and frequent interaction by means of a shared body of verbal signs," also affirms that "linguistic communities may consist of small groups bound together by face-to-face contact or may cover large regions, **depending on the level of abstraction we wish to achieve**." Hockett (1958: 8), in turn, states: "some speech communities of today are extremely large. English has several hundred million native speakers, and millions with some other native language have learned English for business, professional, or political purposes. Russian, French, Spanish, German, Chinese, and a few others also have vast numbers of speakers." Thus, when thinking of language on a macro level, as a political organism and a system sharing general formal similarities, both Gumperz and Hockett come to the same conclusion and capture the feeling of community, despite the fact that their thought is guided by theoretical paradigms with different primary focuses.

Each of the Portuguese-speaking countries contains various other speech communities. The internal structure of each group depends on the existent linguistic varieties, the role of these varieties in linguistic interaction, the symbolic role they play, and the social evaluation of the linguistic differences involved.

Brazil, for example, is a country of enormous dimensions, with an area of 8 511 965 km^2 that represents 48.33% of South America. It constitutes a macro speech community of about 180 million speakers, the vast majority of whom have Portuguese as their mother tongue and their official language, for whom it is also the language of media, government, and education (Scherre, forthcoming). Thus, Brazilians posses a system of verbal signs used in normal face-to-face interaction that marks their identity and establishes symbolic integration. With respect to the characterization of the notion of speech community, all of these facts serve as clear illustrations of the applicability both of the positions of Bloomfield, Hockett, and Lyons on the one hand, and of Gumperz, Hymes, and Fishman on the other.

As in other communities in which the standard language, or the codified norm, is more a function of social class than of interactional context, in Brazil we find so-called instruction in the mother tongue, or teaching of Portuguese for students whose first language is Portuguese. In fact, what is taught is the normative or standard grammar of Portuguese, using pedagogical textbooks based on certain European norms that are not valid even for contemporary Brazilian written texts. Because standard Portuguese is the collective reference and goal, many Brazilians exhibit low linguistic self-esteem, revealed by social attitudes and linguistic evaluations such as *falo português errado* 'I speak wrong Portuguese' or *o português é uma língua difícil* 'Portuguese is a difficult language.' Furthermore, most Brazilians exhibit overt evaluative behavior with respect to features that are indicators of social class. They reject regular variable linguistic phenomena that are more frequent in the speech of people without social prestige, such as variable number concord, or in country speech, such as the retroflex realization of /r/. Thus, in addition to 'orderly heterogeneity,' Brazil also shows 'a set of social attitudes towards language' that are uniform and function as additional features of identification within the Brazilian Portuguese speech community. These facts serve as clear illustrations of the applicability of Labov's definition of the speech community.

Brazil also has other speech communities formed by small indigenous populations, with a total of

about 230 000 speakers and 190 languages, and by the descendants of immigrant workers who came to Brazil after the 18th century and, with varying degrees of success, attempted to maintain a symbolic link with the homeland, most notably through the use of German, Italian, and Japanese. According to Rodrigues (2000: 10), the most widely spoken minority language in modern Brazil is Japanese, with an estimated 400 000 speakers (0.24% of the total population), while the indigenous languages with the greatest number of speakers are Guaraní, with about 30 000 speakers (0.018%), Tikúna, with about 23 000 speakers (0.014%), and Kaingáng with about 20 000 speakers (0.012%). Rodrigues (1986: 83–86) states that to the northeast of the Amazon Basin there is collective and individual multilingualism. In this region, people of the Eastern Tukáno indigenous group normally speak three to five languages, and some have mastered eight to ten languages. In this region, one of the social norms, having the function of facilitating interaction and identification of the indigenous groups involved, is knowledge of several languages with no language mixture. For the characterization of this speech community, the definitions of Gumperz, Hymes, and Fishman seem more relevant. Nonetheless, Labov's position, especially with respect to "a set of social **attitudes** towards language" is clearly applicable. Because language is a strong mark of cultural identity for them and because they consider their own language to be 'the good language', indigenous speakers also exhibit "**overt types of evaluative behavior,**" without a codified norm (Emmerich, 1991). This is a matter of norms within the speech community, and not of mere normative patterns, as pointed out by Eckert (2000: 31) in her discussion of Romaine's (1982) critique of Labov.

Guinea-Bissau, with about one million inhabitants on its 36.125 km^2 of West African soil, illustrates another type of Portuguese language speech community that validates the definitions discussed above in the 'Summary of Speech Concepts' section. According to Couto (1994: 45–46), alongside Crioulo Upper Guinea, a Portuguese-based Creole, there are more than 15 African native languages in the country, including Fula, Balanta, Mandinga, Manjaco, and Papel. Crioulo Upper Guinea is spoken by more than 50% of the population as a contact language, especially in the cities and surrounding areas, and by about 10% as the vernacular language. Portuguese itself is the official language, the language of the schools, and the language of the government. Couto (1994: 45) states: "The entire history of Guinea-Bissau is written in Portuguese." Guinea-Bissau acts as and is identified as a speech community in which group identity is established through the mother tongue, symbolic integration is established by the official language, and inter-group communication is made possible by a contact language. Thus, there are linguistic and social norms shared by the community members.

Rupture, Creation, and Continuity of Speech Communities

Brazil and Paraguay – two large speech communities within South America – constitute good examples of mobility of social groups and consequently of speech communities. This sort of mobility is present in all human groupings, but becomes more significant in countries that undergo invasions with subsequent restructuring on the ethnic, ethical, cultural, religious, and linguistic levels.

Invaded in 1500, Brazil was home to millions of indigenous people and possessed a vast richness of linguistic diversity. According to Rodrigues (1986: 18–19), hundreds of different languages were spoken at the time and, although there are still about 190 of them left, they are totally unknown to most Brazilians. Nowadays, there are only small indigenous communities. Brazilians now consider their country to be completely monolingual in Portuguese, but it has in fact always been basically multilingual, and Portuguese had not yet achieved dominance as late as 1750. In the region of São Paulo, the Língua Geral Paulista was widely spoken, as was the Língua Geral Amazônica in the North, although it is today found only in small areas under the name Nheengatu, or 'good language' (Rodrigues, 1996). History attests the dominance of versions of Língua Geral throughout all social levels and in both the private and public spheres. Portuguese "was learned by those few who attended Catholic schools and was used in written documents and in ceremonies, having more of an official than a public character" (Villata, 1998: 33). In this context, "the Portuguese made an effort to alter symbolic meaning of Portuguese language prior to the actual separatist moves, when the Amerindian language was recognized as a useful vehicle for signaling the distinctiveness of the Brazilian nation-state" (Urban, 1994/1991: 325). The use of indigenous-based Língua Geral was forbidden, with heavy linguistic repression beginning in the second half of the 18th century. The presence of other languages was again repressed in the first half of the 20th century through the proscription of teaching and use of the native languages of European immigrants. Thus, in the context of the upheaval created by the European invasion, there was a reorganization of speech communities, with the imposition and appropriation of Portuguese as the mother tongue due to

linguistic repression, together with two further developments with significant import on the social plane: the removal of the Portuguese royal family to Brazil in 1808, and the institution of Portuguese as the official language in 1890 (Bortoni-Ricardo, 1985: 14–21).

The structural boundaries between Brazilian Portuguese sociolects and dialects are not clearly demarcated. Bortoni-Ricardo (1985: 9–10) notes that, in Brazil, "most of the nonstandard features of the language are characteristic of gradient rather than a sharp stratification." One may say that linguistic varieties form a continuous ramp. There is mutual intelligibility from north to south, from east to west, even at the end-points of the rural/urban continuum, represented, on the one hand, by speakers with little or no education from isolated rural communities and, on the other hand, by urban speakers with 15 or more years of schooling. Although communicative misunderstandings may occur, the differences on the social and regional axes impede communication no more than do differences in vocabulary among different professions in urban areas.

Paraguay's linguistic history is partially different from that of Brazil. Although both countries started out with similar linguistic constellations, they are now radically different. Colonizers brought Spanish to Paraguay, and from the resultant contact a Língua Geral based on Guaraní emerged. This modified version of Guaraní – Guaraní, Paraguayan – is now the mother tongue of 90% of the population. It is the pride and joy of the nation and is a basic element in Paraguayan identity. Together with Spanish, the first official language, Guaraní – elevated to status as an official language in 1991 – now functions in all spheres of life. Urban affirms (1994: 310) that in Paraguay the situation is: "two languages/one social group identification." He goes on to state that "approximately (...) one half are fluent in both Spanish and Guaraní, with the majority of the remainder (40–45%) being monolingual in Guaraní, with only a small portion (<10%) monolingual in Spanish." This is quite different from the situation in Brazil, where, beginning in 1750, in Urban's terms (1994: 313), "the semiotic pressure to project a one language/one culture/one people relationship" has prevailed. What happened in Paraguay involves the continuity of the speech community, broadened by the presence of Spanish, without the dramatic rupture that occurred in Brazil. Urban (1994: 325) states that, "in Paraguay the Spanish did not move decisively against Guaraní, although they had moved against the Jesuits and, hence, against the Indians. At the time of independence in 1811, the indexical value of Guaraní was in keeping with its symbolic value. It was spoken by a majority of Paraguayans."

Final Remarks

In the 'Summary of Concepts' section, I presented an overview of three lines of definition of the concept of the speech community, all of which attempt to capture the complex linguistic and social networks typical of human agglomerates. Many scholars have discussed the concept of speech community and especially Labov's view of it. Milroy (1980), for example, argues that the concept of social class is fundamental in the implementation of Labov's definition, but does not capture the reality of certain communities that function in terms of 'local loyalty'. For such communities, according to Milroy (1980: 14), "membership of a group labeled 'lower-middle class' does not necessarily form an important part of a person's definition of his social identity. Yet smaller-scale categories are available to which people feel they belong and which are less abstract than social classes." Milroy (1980: 14) proposes that the term *community* should be limited to "cohesive groups to which people have a clear consciousness of belonging." Nonetheless, Milroy's (1980: 18) most basic insight is that in these communities speakers "perceive their language or dialect as a powerful symbol of group identity, despite long-term pressures from the standardized code." It is the local language that functions as an index of **symbolic integration**, and not the standard language or standardized code. Milroy (1980: 17–18) cites as examples "working-class communities" in Norway and "low-status" Belfast speakers. Furthermore, she states "examples can be quoted as divergent as Lowland Scots in Southern Scotland, Catalan in Spain, Canadian French in Canada, Black English in United States, and the whole range of low-status vernaculars in British and European cities." Although social class may not be the best parameter for analysis in these cases, it is clear that both "a set of social **attitudes** toward language," in the terms of Labov (1975: 248; 1989: 2), and the existence of **orderly heterogeneity** are fundamental in attempting to capture the feeling of speech community in these groups. Milroy's (1980) considerations thus reinforce the view that no single definition can account for the whole of reality insofar as speech communities are concerned; scholars must seek out complementary aspects of the definitions if their goal is to understand the whole set of linguistic phenomena. Hudson (2001: 27) advocates a similar perspective when he states that all of the definitions we have considered "are 'correct,' since each of them allows us to define a set of people who have something in common linguistically – a language or dialect, interaction by means of speech, a given range of varieties and rules for using them, a given range of attitudes to varieties and items." Thus,

each scholar makes a relevant contribution to the construction or identification of the intricate mosaic made up of people, language, and society.

Speech Development

K Nicolaidis, Aristotle University of Thessaloniki, Thessaloniki, Greece

© 2006 Elsevier Ltd. All rights reserved.

The development of speech occurs over several years, typically commencing with the prelinguistic speech-like vocalizations at infancy and continuing with speech production and the refinement of phonetic abilities throughout childhood.

To date, the study of speech development has been challenging due to, among other things, the necessity for multidisciplinary scientific input, the importance of generating comprehensive and explanatory theoretical frameworks, and the innovative methodological procedures required for experimentation with infants and young children. Research has tried to shed light on the contribution of neural, motoric, perceptual, cognitive, anatomical, linguistic, emotional, and social parameters guiding the ontogenetic

path of speech. Some of the core theoretical questions that have been addressed include the following:

- To what degree can the development of spoken language be attributed to innate knowledge and universal language properties vs. constraints imposed by the child's biological and cognitive systems as well as the linguistic and social systems to which he or she is exposed?
- How does anatomical/physiological and motor skill maturation influence speech development?
- How does the infant enter the speech code?
- How do ongoing changes in the perceptual abilities of children influence the development of speech?
- How are speech perception and production shaped by the ambient language?
- What is the size of the early units of speech (i.e., words, syllables, segments, and gestures)?
- Is there continuity between prelinguistic vocalizations and subsequent developments in speech production?
- What is the phonetic content of children's productions?
- How does the emergence of phonological systematicity influence children's speech output?
- What is the order of acquisition of particular sounds?
- What is the temporal extent of speech development?

The development of speech production requires mastery of perceptual and motor skills by the child. The following sections present some of the developmental milestones in the perceptual and production abilities of infants and children in light of selected key factors (e.g., anatomical constraints and experience with the native language) that influence in important ways the development of this unique human capacity. The discussion follows advances in the acquisition of segmental and prosodic components of speech during the first year of life and throughout childhood.

Anatomical/Physiological Maturation and the Development of Speech

Important developments in anatomical and neurophysiological structures occur during infancy and childhood. Over time, maturation of the functions of the nervous system, the auditory system, and vocal tract subsystems relate to significant developments in the perceptual and production abilities of children; these gradually approximate and eventually reach the abilities of adult speakers.

The vocal tract anatomy of infants up to 3 months is substantially different from that of adult humans and resembles more closely that of nonhuman primates. Some of its major characteristics include (a) a gradual rather than a right-angle bend of the orophrarynx, (b) an elevated position of the larynx that results in a short vocal tract and a close approximation of the epiglottis to the velum (the so-called engagement of the larynx and velopharynx), (c) a short pharyngeal cavity and a relatively broader oral cavity compared to the adult one, and (d) a large tongue in relation to the size of the oral cavity.

These major differences between the infant and adult vocal tract have important consequences for the first vocalizations that infants make. The close proximity of the laryngeal and velopharyngeal structures leads to nasal vocalizations. The size and placement of the tongue, in addition to immaturity of its intrinsic musculature, result in a very restricted set of sounds mainly produced by front–back piston-like tongue movements.

A major landmark in developmental anatomy begins at approximately the fourth month of age when there is a restructuring of the vocal tract that starts to resemble that of the adult human. The facial skeleton grows downward and forward, increasing the size of the vocal tract and allowing the tongue to move more freely. In addition to the dramatic changes in vocal tract structure, which result in the production of a larger variety of sounds, maturation of the intrinsic muscles of the tongue allow more refined lingual movements and shapes during sound production. Further, greater influence of the supralaryngeal muscles on the vocal folds allow increasing contrasts of pitch. During this period of vocal play, the infant explores the vocal tract and updates sensory information about the changes occurring in the oral and pharyngeal cavities.

The development of the vocal tract continues throughout childhood. As the child grows older and his or her body size increases, the musculoskeletal system that underlies speech production develops considerably. Descend of the laryngeal cartilages into the pharynx and changes of their positioning continue during the first 5 or 6 years. A major change relates to the significant increase in the length of the vocal tract; data on 8- and 12-year-old girls, for example, suggest a 10–15% increase in vocal tract length between these two ages (Goldstein, 1980). Growth of vocal tract structures, development of the respiratory system, development of motor skills, and increased experience with the spatiotemporal properties of speech production relate to ongoing changes in articulatory patterning and the acoustic characteristics of speech during childhood.

Significant developments in the nervous system also occur during infancy. A left hemisphere bias for auditory speech sound processing appears as early as

the third month of age. General maturation of the motor regions of the cortex that support infant vocalizations occur during the fist year of life. Important landmarks in infant vocalizations (i.e., cooing, babbling, and the onset of meaningful speech) have been associated with discontinuities in neural and/or vocal tract development (Kent and Miolo, 1995).

Infants' special sensitivity to speech may also relate to the development of the auditory system. The onset of auditory functioning occurs during the last trimester of gestation and provides newborn infants with prenatal experience with some properties of human speech. The fetus is mainly exposed to the prosodic characteristics of human speech as its mother's body acts as a low-pass filter (i.e., allowing low but attenuating high frequencies). Such prenatal *in utero* experience may be responsible for the preference infants show toward human speech but also a bias toward the voice of their mother and the prosodic patterns of her native language. Maturation of the auditory system occurs over time and may to some degree be responsible for differences in the perceptual mastery of some speech sound contrasts.

The Speech Signal and the Infant: Challenges and Early Perceptual Capacities

Fluent speech is continuous and highly variable. Several words may be produced without interruption, but the adult listener can segment and recognize individual words relatively effortlessly. The lack of clear or reliable boundaries between words in the speech signal constitutes a fundamental challenge for the infant, who needs to segment the continuous stream of speech in order to extract words and understand meaning. This segmentation problem is further intensified by the large variability present in the speech signal. This can be due to interspeaker differences in production (i.e., variability among speakers of the same or different age or sex); it can also be due to variability among utterances of the same individual due to contextual effects, prosodic factors such as stress position, rate effects, environmental conditions such as the presence of noise, emotional state, and so on. The task of the infant is to recognize the underlying similarities in sound patterns and identify different productions of the same token as the same word.

Speech perception by the adult listener is greatly facilitated by the redundancy present in the speech signal. Even in the presence of adverse conditions (e.g., noise), parts of the signal may be recovered as the listener utilizes acoustic information shared by neighboring regions of the signal and integrates this with linguistic and conceptual knowledge. At the early stages of language learning the young listener lacks such top-down processing capacities while the presence of variability in the speech signal may further complicate the perceptual process.

Despite the challenges the acoustic signal presents to the infant, speech perception research during the past 30 years has shown that the infant possesses a remarkable capacity to discriminate phonetically relevant acoustic contrasts from the first weeks of life. This impressive ability is founded in the presence of two early perceptual capacities, categorical perception and perceptual constancy, which assist the infant in discriminating speech contrasts and in ignoring nonsignificant variation in sound production. Experimental work has provided evidence that infants, similarly to adults, perceive consonantal contrasts (in place, manner, and voicing) in a categorical manner. Categorical perception refers to the ability to discriminate easily among sound differences across categories but not within categories and is advantageous since sensitivity to cross-category differences will assist the listener in learning the contrastive sounds of his or her language. At the same time, insensitivity to within-category differences helps the listener cope with variability during different productions of the same sound. Furthermore, perceptual constancy enables listeners to treat sounds as similar despite changes that may have a considerable influence on their acoustic characteristics (e.g., a change in speaker or rate). Experiments have shown that infants can normalize for talker differences during the perception of vowels – that is, they can perceive the same vowel spoken by male speakers, female speakers, and children. They can also compensate for changes in speaking rate and context in the perception of some consonantal contrasts (see Vihman, 1996). Such a perceptual capacity will assist the infant to disregard linguistically irrelevant variation and relate differences in speech sounds to differences in meaning. Evidence of categorical perception and perceptual constancy at infancy indicates that babies enter the world equipped with those perceptual capacities that enable them to begin processing the speech signal, cope with some significant aspects of variability in speech, and make distinctions that are necessary for speech perception.

Speech Perception by the Young Listener: The First Year and Beyond

Impressive perceptual achievements together with dramatic changes in infant speech perception mark the first year of life. During the first 6 months infants show the capacity to discriminate many native and nonnative speech sound contrasts and potentially any

sound contrast found in the world's languages. Infants can discriminate voicing contrasts, place and manner of articulation distinctions, as well as vowel contrasts. An early ability to discriminate prosodic features, such as differences in intonation and stress patterns, is also evident (for a review of studies, see Jusczyk, 1997).

Following an initial language-general perceptual capacity, a shift toward a language-specific pattern in speech perception occurs. Increasing experience with the ambient language leads to a decline in sensitivity to nonnative contrasts, which occurs earlier for vowels (by 6 months of age) than for consonants (in the latter half of the first year). Kuhl (1993) claimed that as infants gain experience with tokens of the native vowels they reorganize an initially universal vowel space divided by universal psychoacoustic boundaries to a language-specific one. Organization of native vowel categories occurs around prototypes (i.e., instances that are more central or typical) that act as 'perceptual magnets' attracting surrounding vowels and warping the perceptual space. The perceptual magnet effect may explain the decline in sensitivity to nonnative vowel contrasts as the strong perceptual pull of prototypical on less prototypical vowel tokens inhibits discrimination. Infants exposed to different languages show this effect only for their native language vowels; thus, experience with the ambient language helps the infants to organize their vowel space so as to include the categories that are typical of their native tongue.

A gradual decline in the sensitivity to some nonnative consonantal contrasts occurs in the latter half of the first year (Vihman (1996) and Jusczyk (1997) provide a review of research findings). For instance, English learning infants can discriminate selected Hindi and Nthlakapmx (Thompson) contrasts at 6–8 months; fewer are able to do so at 8–10 months and hardly any at 10–12 months.

While a decline in sensitivity to nonnative contrasts is evident, infants between 6 and 9 months of age demonstrate sensitivity to phonetic, phonotactic, statistical, and prosodic properties of the native language. For instance, infants prefer words that contain native and more frequent segments. English-learning infants prefer words with the predominant trochaic (strong/weak) stress pattern of their mother tongue. During this period, infants also develop the capacity to segment the input into distinct words implementing multiple cues. Research has shown that at 7½- to 8-month-old English-learning infants rely on prosodic information such as the predominant metrical pattern of their language (i.e., trochaic) and statistical/distributional information present in the input to identify word boundaries. Further cues are exploited subsequently between 9 and 10½ months, when infants use allophonic and phonotactic information to locate boundaries and extract words (Jusczyk, 1999).

The previous discussion indicates that developmental changes in speech perception culminate in the latter half of the first year. Several concurrent events appear to be closely linked and can function to facilitate acquisition of the native language. Attenuation of sensitivity to nonnative contrasts occurs at approximately the time when receptiveness to the structural properties of the native language increases. These changes indicate that infants begin to tune into the sound patterns of the native language. Perceptual reorganization involving loss of categories that are infrequent in the input can facilitate the learning of language-specific phonological contrasts. The infant's increasing sensitivity to structural and statistical regularities of the native language facilitates segmentation and extraction of words from fluent speech. Indeed, all this occurs at the same time as another major developmental landmark – the onset of word recognition at approximately 8–10 months. As infants improve their segmentation abilities and recognize a larger number of words, the store of lexical items in the mental lexicon increases. All these milestones have important consequences for further developments in language acquisition in the second year of life, when meaning and intentional communication become increasingly important for the child.

Children's speech perception capabilities continue to develop after the first year. Some of the factors that influence later developments in speech perception relate to maturation of the auditory system, the link between the perceptual and production capacities of the child, as well as linguistic and cognitive development.

Attainment of the complete set of language-specific phonemic contrasts is gradual and adult-like perceptual patterns appear at approximately 4 or 5 years. Children may encounter difficulties with some phonemic contrasts; for instance, /θ/ and /f/ or /r/ and /w/ remain difficult to discriminate at age 3 and beyond. Differences in the placement of phonemic boundaries between adults and children also exist. Boundaries are refined as children grow older; for instance, differences in the placement of the /r, w/ phonemic boundary reduce with the increasing age the child (i.e., from 3 to 5 years). A reduction of the voice onset time (VOT) difference needed for the discrimination between voiced vs. voiceless stops also occurs with age; perception becomes adult-like at 6 years of age (see Vihman (1996) for a review of the studies).

Developmental changes in how children process speech also occur. For example, children in their

second year of life begin processing speech incrementally, i.e., they become able to recognize words using partial (word initial) phonetic information. This is a characteristic of adult speech processing and its development in children relates to lexical growth. Differences in cue weighting strategies between adults and children are also evident. For identification of the /sV/ vs. /ʃV/ contrast, adults appear to give more weight to the spectral characteristics of the fricative noise, whereas children give more weight to the vowel-onset transitions (Nittrouer, 1996). Such evidence may relate to the adoption of more global perception strategies by children vs. more analytic ones by adults, necessitating the use of more vs. less transitional information, respectively.

Interest in the perceptual developments of children older than 1 year has in part arisen as a consequence of research interest in understanding children's production errors. Children's mispronunciations could potentially be related to a misperception of adult words and therefore to differences in word representation. However, evidence indicates that children can perceive contrasts they cannot yet produce and may also make relevant distinctions in their productions, although these may be different from adult contrasts.

Units and Representations

Two major candidates for infants' early representational units of speech have been suggested: the syllable vs. a smaller sized unit, namely the segment or feature. The remarkable abilities of very young infants to discriminate a variety of speech sounds initially led to interpretations that assigned considerable phonetic detail to infant representations. It was suggested that infants could discriminate segments or features. However, different interpretations were possible for some of the findings; for example, infants may detect differences between stimuli because they pay attention to particular parts of the whole syllable; a simple detection of differences between stimuli does not presuppose a detailed analysis of such differences. An alternative account has recently favored the syllable as the unit of representation and perceptual processing. Jusczyk (1997) reviewed findings of several studies and suggested that there is no evidence to indicate segmental representation of speech in the first 6 months of life; for instance, studies have shown that newborns can detect changes in the number of syllables but not in the number of segments. Further arguments in favour of the syllable are reviewed in Vihman (1996), together with experimental findings that have been inconclusive, making it difficult to draw firm conclusions about the size of the early representational units of speech.

Onset of word comprehension at 8–10 months is associated with the beginnings of the formation of a lexicon in the latter half of the first year. Although little is known about infants' early representations of words, it has been suggested that these may not be fully specified in terms of phonetic detail because a small lexicon does not require detailed representations for successful discrimination between the lexical items stored. The word or syllable may thus be the early perceptual unit. As the lexicon expands, more fine-grained details are necessary for lexical differentiation and thus representations in terms of segments or features are required. A relationship between lexical density and the level of detail in representation of lexical items has thus been suggested.

The word as the first production unit (i.e., the unit of contrast in a child's early phonological organization) has also been put forward. Progression toward the segment as the unit of phonological organization relates to vocabulary growth and occurs over time (Studdert-Kennedy, 1987). The emergence of phonemic units may occur in a self-organizing way (see models by Kent (1992) and Lindblom (1992)). The relative early disappearance of phonological processes that apply to the whole word and the persistence of processes that apply to individual segments may be interpreted to suggest the emergence of segments as organizational units over the course of the first years of life (Vihman, 1996).

In line with this, accounts of the developmental course of motor skill maturation and coarticulatory patterns have argued for an initial larger-sized speech production unit (i.e., the syllable) and the gradual emergence of smaller sized units (i.e., gestures). Babbling and first word production can be viewed as organized over the holistic, undifferentiated syllable resulting from recursive global opening and closing gestures of the vocal tract (MacNeilage and Davis, 1990). As the need for greater differentiation of movements arises so that the repertoire of words is increased, productions become more refined and greater variation in articulatory gestures is achieved. Maturation of motor skills and practice with new articulatory movements gradually lead to the production of independent gestures that can be coordinated with other gestures. Advances in the combination of gestures and their appropriate spatiotemporal organization occur over time and eventually lead to adult-like performance.

Speech Production: The First Year

During the first year of life, the vocal development of infants shows regularities that have been chronologically demarcated in stages. These regularities occur

for the majority of normally developing infants irrespective of language background, although there may be individual variability and overlap in the vocalizations appearing between stages. Transition between stages is thus typically not abrupt and the onset of a new stage is marked by the introduction of new types of vocalizations. Several stage systems have been proposed (for a summary, see Vihman (1996) and Kent and Miolo (1995)) and the following description draws primarily from Oller (1980), Stark (1980), and Locke (1983):

- Stage 1 (0–2 months): This period is associated mainly with sounds indicative of discomfort or distress, such as cry and fussing, and 'reflexive' vocalizations, such as grunts, coughs, and burps, attributed to involuntary motor patterns and in general immature control of bodily functions. Although speech-like vocalizations are rare, some nonreflexive, nondistress sounds do occur, usually produced with normal phonation but limited resonance and resembling nasalized vowels or syllabic nasals.
- Stage 2 (2–4 months): Known as the 'cooing and laughter' stage, this period is characterized by the appearance of the first comfort sounds produced voluntarily, usually in interaction with a caregiver. Vocalizations are typically produced at the back of the mouth due to the proximity of the tongue and palate in this area and may include velar consonant-like (fricative) sounds. Toward the end of this stage, the appearance of sustained laughter emerges.
- Stage 3 (4–6 months): During this period of 'vocal play,' the infant explores a whole range of the sound production possibilities offered by its vocal tract. This period is characterized by the infant's increasing control over the laryngeal and supralaryngeal structures and a marked increase in supraglottal constrictions. Vocalizations include yells, squeals, and growls resulting from manipulation of intensity and fundamental frequency. Exploration of periodic and aperiodic sound sources and consonantal constrictions result in the production of a variety of sounds, including bilabial and ingressive uvular trills ('raspberries' and 'snorts') as well as various friction noises and nasal murmurs. This period also marks the onset of vowel sounds that are more adult-like and of marginal babbling consisting of rudimentary consonant–vowel syllables that lack the temporal regularity of canonical babbling.
- Stage 4 (6–9 months): This period of 'canonical' babbling is characterized by the production of consonant–vowel syllables with regular timing characteristics. Temporal regularity is achieved by the cyclic alternation of closing and opening gestures producing consonant–vowel sequences resembling syllable production by adults. Both single consonant babbling (e.g., [ba] and [da]) and reduplicated babbling (e.g., [mama] and [bababa]) can occur. Although these reduplicated sequences may sometimes resemble words of the native language of the infant, there is no evidence that the child has assigned meaning to these sequences, and they cannot therefore be considered to constitute words.
- Stage 5 (9–14 months): The 'variegated babbling stage' is marked by the onset of more complex vocalizations in the form of sequences of CV syllables produced with an alternation of different consonants and vowels. During this period, reduplicated babbling also occurs. A considerable increase in the proportion of variegated babbling takes place at approximately 12–14 months, when infants produce long sequences with distinctive sentence-like intonation patterns. This is known as 'jargon babbling,' and the overlaid intonation pattern resembles the production of statements or questions in adult speech. It is at this time that the onset of word production also occurs.

Note that the claim that stages 4 and 5 are sequential (i.e., that the stage of reduplicated babbling is followed by a stage of variegated babbling) has been challenged by research showing that already from the onset of multisyllabic babbling (i.e., between 6 and 9 months), there is considerable overlap between reduplicated and variegated babbling. A single stage (6–12 months) in which reduplicated and variegated babbling develop in parallel has been proposed by Kent (see Kent and Miolo, 1995).

The Phonetic Content of Early Vocalizations

Anatomic–physiological factors constrain vowel production during the first year of life. Although considerable variability in individual patterns has been noted, a predominance of fronted, central, or lower vowels has generally been reported in infant productions (but note the high frequency of back vowels at the cooing stage due to the anatomy of the vocal tract and the back resting position of the tongue during vocalizations from a mainly supine position). The high vowels /i/ and /u/ are generally not frequent in babbling, possibly due to their dependence on vocal tract restructuring and the formation of two distinct vocal tract cavities. The infrequency of back vowels may also relate to increased coordinative requirements between the lips, tongue, and jaw. In

general, a change from a more centralized to more spread out vowel space has been noted toward the end of the first year.

The development of consonant production in the first year of life is marked by a change from laryngeal to supralaryngeal constrictions and from back to more anterior articulations. Although glottal [h, ʔ] and velar/uvular consonants are typically more frequent in earlier stages, during the second half of the first year there are marked changes in consonantal frequency. The most frequent consonants in infant babbling are stops (e.g., b, p, and d) and nasals (e.g., m and n). The glottal [h] appears in high frequency, continuing its presence from earlier stages. Manners such as liquids, fricatives, and affricates are infrequent. A predominance of anterior sounds, labials and alveolars, over velars is also evident (Locke, 1983).

A further significant change that occurs during the first year relates to the vowel-to-consonant (V-to-C) ratio. Vowels predominate in the earlier stages and gradually reduce to reach a 2:1 V-to-C ratio toward the end of the first year. This ratio is still high compared to adult speech, indicating a predominance of vowels in infant vocalizations. The most frequent syllabic frames that accommodate vowel and consonant production are V and CV (see Kent and Miolo (1995) for a review of relevant literature).

A tendency for certain co-occurrence patterns between consonants and vowels has also been observed in babbling (i.e., co-occurrence between front consonants with front vowels, back consonants with back vowels, and labials with central vowels). Such patterns can be modeled in terms of biomechanical constraints on the speech production mechanism. According to the frame/content theory (MacNeilage and Davis, 1990) cycles of mandibular oscillations in babbling serve as the syllabic frames onto which segmental gestures (i.e., syllabic content) are overlaid. Co-occurrence patterns are due to coordination constraints between the lips, tongue, and jaw; these limit articulatory changes within or between syllables.

Finally, there is evidence that the ambient language influences production during the prelinguistic period (see review of relevant findings in de Boysson-Bardies (1999) and Jusczyk (1997)). Prosodic aspects of vocalizations appear to show effects from the native language from very early on. Adults can recognize vocalizations of 8- and 10-month-old infants learning French from those of infants learning Arabic; discrimination is based on features such as phonation type and pitch characteristics. A predominance of falling patterns produced by English-learning infants but evidence of rising patterns by French-learning infants during reduplicated vocalizations suggests influence from the dominant intonational patterns of the native language. Differences in the vowels, consonants, and syllable structures produced by infants from different linguistic backgrounds have also been found to correspond to tendencies of the native language. An influence of native language input on consonant–vowel co-occurrences has been noted; for instance, Swedish infants' production of alveolar stops occurs with a variety of vowels and not just front vowels, as in the productions of infants in other languages. These findings indicate that in addition to biomechanical constraints on the speech production system, experience with the language plays a significant role in the sound co-occurrences produced by infants.

From Babbling to Speech

Opposing accounts have been proposed for the period marking the development from babbling to the onset of first words. Jakobson's (1941) well-known discontinuity view was founded on claims that (a) babbling was prelinguistic and completely unrelated to the onset of meaningful word production and subsequent phonological development; (b) a silent period could sometimes intervene between these two developmental stages; (c) the repertoire of sounds in babbling was random and extremely varied, consisting of any possible human sound; and (d) the majority of these sounds disappeared in the production of first words. Recently, the discontinuity view has been critically challenged and evidence has accumulated in support of continuity between babbling and early word production. Evidence of temporal overlap between babbling and first word production in the speech of many children has disconfirmed the postulation of an intervening silent period. Continuity is supported by the close relationship between the sound repertoire of babbling and early word production. The most frequent consonants in babbling also occur most frequently in early word production; fricatives, affricates, and liquids, which are the least frequent consonants in babbling, are also infrequent in early word production (Locke, 1983). Prosodic continuity between babbling and early word production has also been documented.

However, a decrease in the frequency of alveolars and an increase in the frequency of labials in early words compared to babbling may be considered as evidence of regressive behavior, supporting a discontinuity view (MacNeilage *et al.*, 1997). This suggests that although there is undoubtedly a close relationship between sounds and sound patterns in early word production and babbling, there are some instances of dissimilarity between these two developmental stages possibly attributable to the adoption of simpler articulatory patterns at the time when

there is increasing emphasis on using sound to convey meaning. At the same time, new developments can be expected in the sound repertoire of early words as the need for more distinctions in meaning arises. For instance, a more expanded vowel space is exploited in early words, resulting in an increase in the vowel types used and the inclusion of high front and back vowels. The overall characteristics of babbling (including rhythmicity, the opportunity it offers infants for repetitive practice and feedback, and its phonetic content) contribute to subsequent developments in spoken language.

Speech Production after the First Year: Toward Phonological Systematicity

At the end of the first year, impressive qualitative and quantitative changes in the vocal repertoire of infants occur. This period is marked by an increase in the frequency of babbling, the appearance of protowords, and the first real words. Adult-like jargon sequences with no consistent form or meaning can co-occur with protowords (i.e., forms that display some phonetic and semantic consistency but have no clear relationship to adult target words), as well as first words, which relate to the adult word model relatively consistently in terms of form and meaning. Examples of early words produced by 10- to 15-month-old infants from various linguistic backgrounds (English, Swedish, German, Japanese, etc.) and of protowords are provided in Vihman (1996: 242–248). Some sample forms include: protowords by English-speaking children: [pwi], [ʔʌgæ]; early words in English: [gaga], [dɔgi] for doggie, [be(be)], [pipe] for baby; French: [(h)ailo] for allo 'hello,' [ta] for tiens 'here'; Japanese: [wawa] for wanwan 'doggie,' [koje] for kore 'this'; Swedish: [gɔ:ka] for klocka 'clock,' [bɔmbə] for blomma 'flower.'

Despite the lack of a clear temporal boundary between babble and speech due to the co-occurrence of forms, a transition toward intentional communication is evident in this period, with advances in the referential use of words generally occurring in the second year. The first 50-word period (approximately 1 year [1;0] to 1 year 6 months [1;6]) is marked by phonetic variability in the production of words and lack of systematic sound contrasts. Contrasts may begin lexically (i.e., they appear between whole words) and generalize gradually. Early words show an increase in the use of 'true' consonants (i.e., consonants other than glottals and glides), a higher frequency of labials, and a higher frequency of stops compared to fricatives. Stops, nasals, and glides are common. Increased frequency and accurate production of the high vowels /i/ and /u/ occurs. The syllable structure is typically simple (e.g., CV and VC); reduplicated CVCV sequences are common for some children. Early word production can include instances of progressive idioms – that is, more advanced forms than the rest of the child's words produced with segmental accuracy, such as accurate production of the [pr] cluster in 'pretty' but not in other words. Such forms can be frequently followed by regression – that is, the production of simpler forms such as [piti] or [bidi] for 'pretty'. Initially accurate productions may relate to children's more advanced perceptual and articulatory abilities compared to their phonological system. Selectivity or avoidance of words is also characteristic of this period as children select or avoid particular words on the basis of their phonological characteristics. Avoidance patterns may relate to words containing sounds not yet available in the child's system, words containing difficult sounds, clusters, or words of particular length. Further developmental changes occur during this period (e.g., increase in the types of sounds and phonotactic structures produced) and reflect emergent phonological organization linked to developments in the mental representation of words.

Following the first word period, progress toward phonological systematicity occurs at the time when there is a rapid growth in productive vocabulary. Children acquire the phonemic contrasts of their ambient language over several years, including their preschool and school years. Mastery of vowels commonly occurs by the end of the third year (see Hanford-Berhardt and Stemberger (1998) for vowel development in a variety of languages). Typically, acquisition of stops, nasals, and glides precedes acquisition of liquids, fricatives, and affricates. Research on English has shown that although by age 4 years, a considerable amount of the native sounds are acquired, mastery of some sounds, such as dental and alveolar fricatives as well as postalveolar fricatives and affricates, occurs well after 4 years and may not be achieved until 7 or 8 years of age. A late development concerns the acquisition of clusters spanning a period from 4 to 8 years. Initial stop + liquid clusters are acquired earlier (4 or 5 years of age) than fricative + liquid clusters in English (7 years of age). Initial three-consonant clusters are also late to acquire (i.e., by 7 years of age) (Stoel-Gammon and Dunn, 1985).

At the same time, children's reproduction of adult words includes systematic changes in target sounds, sequences, and syllables. These can be attributed to immaturity of the auditory and articulatory systems as well as limitations in the processing abilities of children. Such constraints may explain some of the similar patterns that have been observed in children's reproduction of adult words in several languages, indicating some degree of similarity in children's

development of phonological organization. Children's approximations to adult words have been typically described in terms of phonological rules or processes (Ingram, 1986). Although the psychological reality and explanatory power attributed to these processes have been challenged (Stoel-Gammon and Dunn, 1985), they can provide a useful framework for the description of children's reproduction of adult words and for the study of phonological disorders. Recently, emphasis has shifted toward constraint-based theories of phonological acquisition and possible applications in phonological disorders (Hanford-Berhardt and Stemberger, 1998).

Three major categories of processes are usually identified: substitution processes, assimilation processes, and syllable structure processes. The majority of examples presented here are from Yavas (1998), Vihman (1996), and Kappa (1999); their exact transcriptions are reproduced here. Further examples and audio files demonstrating some of these processes are from the 'paidologos' project, which investigates cross-language aspects of phonological development.

Substitution processes involve the replacement of classes of sounds present in adult words by classes of sounds that are part of the child's productive repertoire. Relevant processes within this category include the following:

1. Stopping: Stops replace fricatives or affricates at corresponding places of articulation. The execution of a simpler ballistic movement occurs in place of a more complex fricative articulatory configuration requiring increased articulatory precision and control.
   - English: [tʌn] 'sun,' [dam] 'jam,' [mu:b] 'move'
   - Greek: /'zesti/ → ['deti] 'warmth,' /'feta/ → ['peta] 'slice,' /'kaltsa/ → ['kata] 'sock'
   - Spanish: [sopa] → [topa] 'soup'
   - Turkish: [sen] → [ten] 'you'

2. Fronting: Velar or palatal sounds are replaced by alveolar/dental sounds. More advanced rather than posterior articulations are favored. Fronting of other sounds may also occur.
   - English: [su] 'shoe,' [ti] 'key,' [sɪp] 'ship,' [tʰɛtɪn] 'kitten'
   - Greek: /'kola/ → ['tola] 'glue,' /'sima/→ ['θima] 'sign (n),' /'kasa/ → ['taʃa] 'box of storage'
   - Portuguese: [ʃapew] → [sapew] 'hat'
   - Turkish [ʃu] → [su] 'that'

3. Liquid gliding: Liquids /r, l/ are replaced by glides /j, w/. A more vowel-like articulation results.
   - English: [wæbɪt] 'rabbit,' [wʊk] 'look,' [jʌv] 'love'
   - Greek: [ku'tala] → [ta'taja] 'ladle'
   - Portuguese: [amarɛla] → [amajɛja] 'yellow'
   - Turkish: [para] → [paja] 'money'

4. Vocalization: liquids /r, l/ are replaced by vowels in final position.
   - English: [tebo] 'table'

Assimilation processes refer to contextual influence induced on particular sounds. As a result, segments become more similar to neighboring sounds. In this category are the following processes:

1. Consonant harmony: A change in the place or manner features of a consonantal segment occurs under influence from a noncontiguous consonant. The direction can be either regressive (right to left) or progressive (left to right).
   - English: [pap] 'top', [dɔd] 'dog', [gɔg] 'dog', [lɛloʊ] 'yellow', [meilmaksɨz] 'mailboxes'
   - Greek: /'kato/ → ['kako] 'down,' /so'fia/ → [fo'fia] (proper name), /pe'tai/ → [pe'pai] 'it flies'

2. Final devoicing: Production of a target final voiced obstruent without voicing.
   - English: [bæk] 'bag,' [nos] 'nose'

3. Prevocalic voicing: Production of a target voiceless obstruent with voicing in the context of a following vowel.
   - English: [do] 'toe,' [bi] 'pea'
   - Greek: /to'tos/ → [do'do] (proper name), /'poði/ → ['bodi] 'leg,' /'teseɾa/ → ['deselo] 'four'

Syllable structure processes refer to modifications of the syllable structure of adult words so that complexity is reduced. They reflect a tendency toward the production of basic CV syllables. This category includes the following processes:

1. Final consonant deletion: Final consonants or consonant clusters are deleted in the child's production.
   - English: [kɪ] 'kid,' [dɛ] 'desk,' [mɪ] 'milk'
   - Spanish: [aɾbol] → [abo] 'tree'
   - Portuguese: [lapis] → [lapi] 'pencil'
   - Greek: /fos/ → [po] 'light,' /'kokoras/ → ['kokora] 'rooster'

2. Reduction of consonant clusters: Simplified production of clusters by deletion of one of its members. Usually, the member deleted is a sound that is considered relatively difficult in production and is acquired later in the child's productive repertoire.
   (i) s + consonant: In the /s/ + stop or nasal clusters, typically the /s/ is deleted and the stop

or nasal is produced. Reductions where the /s/ is retained do occur, however. In the /s/ + approximant clusters, either of the members can be deleted.

- English: [tap] 'stop,' [nel] 'snail,' [saɪl] 'smile,' [lɪp] or [sɪp] 'slip'
- Greek: /'spiti/ → ['piti] 'house'

(ii) consonant (not /s/) + approximant: The approximant is usually deleted and the consonant is produced (articulation of /r/ may vary across languages; e.g., tap, trill productions may occur).

- English: [fi] 'free,' [pe] 'play,' [piɹi] 'pretty,' [baks] 'blocks'
- Greek: /klei/ → [cei] 's/he cries,' /'trome/ → ['tome] 'we eat,' ['ce(n)dɹo] → ['cendo] 'center,' /'kitɹino/ → ['titino] 'yellow'
- Portuguese: [bruʃa] → [buʃa] 'witch'
- Spanish: [kɹus] → [kus] 'cross'

(iii) s + stop + approximant: The fricative and approximant are usually deleted in three consonant clusters.

- English: [tit] 'street,' [pæʃ] 'splash'
- Greek: /'kastɹo/ → ['kasto] or ['χato] 'castle'

3. Epenthesis: This involves the insertion of a segment in a word, thus changing its syllabic structure. An alternative strategy for the simplification of clusters can involve the epenthesis of a vowel between the consonantal members of the cluster.
   - English: [bəlu] 'blue,' [pəliz] 'please'
   - Greek: [bluza] → [belula] 'blouze,' [ble] → [bele] 'blue'

4. Unstressed syllable deletion: An unstressed syllable is deleted, especially in multisyllabic words. Both pre- and post-tonic syllables can be deleted. Deletion of unstressed syllables may be due to their reduced perceptual salience compared to stressed syllables.
   - English: [nænə] 'banana,' [tɛfon] 'telephone,' [ɛfənt] 'elephant'
   - Greek: /kara'mela/ → ['mela] 'candy,' /'katse/ → [ka:] 'sit down,' /pa'putsi/ → [ba'bu:] 'shoe,' /paɣo'to/ → [pa'to] 'ice cream'
   - Spanish: [eskoβa] → [kowa] 'broom'
   - Turkish: [ɨspanak] → [panak] 'spinach'

5. Reduplication: Repetition of an adult target syllable in the child's production of a word. This usually results in an appropriate number of syllables but a simplified production of the target word.
   - English: [kaka] 'cat,' [dada] 'dog'
   - Greek: /ki'mame/ → [ma'mame] 'I sleep,' /ka'pelo/ → [pe'pelo] 'hat'

The previous description is not exhaustive. Additional processes applying to a variety of sounds and positions in the word may occur; their frequency may differ among languages. Some examples include the following:

Backing: Anterior dental/alveolar sounds are replaced by velar sounds. Backing of other sounds may also occur.

- Japanese: /tamago/ [kamako] 'egg'

Devoicing: Devoicing of target voiced sounds.

- Greek: ['dama] → ['tama] 'female partner'

Frequently, more than one processes can co-occur in children's productions. For example, the production of target 'cherry' as [dɛwi] involves fronting, stopping, prevocalic voicing, and liquid gliding.

The temporal extent of phonological processes varies. Well-known accounts of the chronology of phonological processes in English include those by Stoel-Gammon and Dunn (1985) and Grunwell (1987). The former provides a categorization of processes into those that disappear by 3 years (i.e., unstressed syllable deletion, final consonant deletion, velar fronting, consonant harmony, reduplication, and prevocalic voicing) and those that persist after 3 years (i.e., cluster reduction, epenthesis, gliding, vocalization, stopping, depalatalization (palatal fronting), and final devoicing). Despite differences in details, many similarities exist between the two accounts and a closer look of the analyses shows that those processes whose domain of application is the word or syllable (e.g., reduplication, consonant harmony, and unstressed syllable deletion) are early processes typically disappearing by approximately the age of 3 years. Processes that affect the segment commonly persist after the third year and some of them can be evident many years later (e.g., 8 or 9 years of age). One of the earliest processes is reduplication, which is common during the first 50-word stage and disappears approximately by age 2 years. On the other hand, stopping is a late process in English and can persist up to 5 years or older for some segments (e.g., /θ, ð/). Gliding of /l/ and /r/ is another late process that can persist beyond age 5 years. Specific clusters (e.g., three consonant clusters) may also be reduced in the speech of some children, aged 8 or 9 years.

Despite similarities between languages, language-specific differences in phonological processes and their chronology exist. For example, whereas gliding of /r/ and /l/ is typical in English, in Italian and Greek /r/ is frequently substituted by [l] (e.g., Greek /'tesɾa/ → ['tesela] 'four'). Differences in the segmental inventories of languages may also relate to differences in the chronology of processes; for example, stopping disappears early in Portuguese but not in English, possibly due to the absence of /θ, ð/ from the consonantal inventory of Portuguese (Yavas, 1998). Furthermore, cross-language differences in the order of acquisition of phonemes may relate to differences in lexical phoneme frequency and phoneme sequence frequency. English children acquire /t/ earlier than /k/, in contrast to Japanese children, who acquire /k/ earlier than /t/. In addition, fronting errors for /k/ are more frequent in English, whereas backing errors for /t/ are more frequent in Japanese. These patterns are in accordance with the higher frequency of /t/ in English and /k/ in Japanese (Beckman *et al.*, 2003). They may also relate to vowel context because back vowels are more frequent in Japanese and front vowels in English (Boysson-Bardies, 1999). The potential influence of vowel context is in line with evidence showing that consonant–vowel sequences in which there is place co-occurrence between the consonant and vowel have higher frequencies than the independent frequencies of their components in adult lexicons in several languages and in children's early word productions (MacNeilage *et al.*, 2000). Such patterns may relate to physiological and biomechanical factors and may explain observed error patterns in English-speaking children (i.e., more errors for /t/ in the environment of back vowels and for /k/ in front vowel contexts). Further research is needed on a variety of languages in order to obtain important insights into the order of acquisition of segments, common vs. language-specific phonological processes, and their temporal extent and to gain an understanding of underlying factors explaining the similarities and differences observed.

Toward Mature Gestural Patterns: Developing Motor Skills and Coarticulation

The development of speech motor skills spans several years and includes advances in motor control, refinement, and adaptation of motor skills at a period when there is ongoing anatomical/physiological and cognitive maturation. Development of movement control for speech production includes advances toward independent control of articulators and the production of gestures that can be precisely coordinated and combined in novel ways. Conclusive evidence is still elusive regarding exactly when the child achieves such independence in articulatory gestures and the coordination needed for mature speech. However, there is evidence that development and refinement of motor skills for speech production does continue throughout childhood and reaches adult levels at approximately puberty. Developmental changes in VOT production highlight the importance of maturing control over different articulatory systems and of appropriate timing of articulatory events. At first, children generally produce short-lag VOTs for all stops. Differentiation between the voiced and voiceless categories is gradual and occurs over time. Research on English-speaking children has shown that after the initial short-lag stage, an increase in the VOT of target voiceless stops occurs, which at the ages of 3–7 is longer than that of adults. Adult-like VOT values for voiced and voiceless stops are reached at approximately 11 years of age. Generally, the voiceless aspirated stops show wide ranges and high variability; such variability decreases between 5 and 11 years of age, suggesting increasing articulatory precision as a result of maturation of motor skills. Such a long developmental course stems from the increased aerodynamic requirements, the simultaneous control required for the glottal and supraglottal systems, and the need for appropriate temporal phasing between articulatory gestures during VOT production.

Further differences in coproduction (i.e., the spatiotemporal overlap between gestures) between adults and children suggest that children need to master the coordination and timing of their articulators so that they produce coarticulatory patterns in accordance with those observed in adult speech. Experimental results have provided varied evidence regarding the degree of coarticulatory effects found in child speech. This may be due to differences in theoretical viewpoint or methodological design. Studies on sibilant–vowel sequences produced by 3- to 7-year-old children and adults showed greater within-syllable coarticulatory effects for younger children compared to older ones and adults (Nittrouer *et al.*, 1989). This is compatible with a view of a larger organizational unit in child speech that is gradually refined into smaller units (e.g., gestures) as motoric skills develop. Production may thus proceed from a more holistic to a more analytic level.

Coarticulatory effects vary as a function of the phonetic identity of segments and therefore the articulators involved in the production of particular sequences. Some gestural patterns may mature earlier than others due to the earlier presence of particular

gestures in the productions of children. For example, gestures for stop-vowel sequences, reflecting opening–closing jaw movements, may be coordinated more precisely earlier. Adult-like coarticulation patterns have been reported for 3- and 5-year-olds for CV sequences with bilabial consonants (i.e., when articulatory gestures for the bilabial and the vowel are not mechanically linked). On the contrary, age-related differences in coarticulatory effects were evident in sequences with /d/ (i.e., when both the consonant and the vowel involved a lingual gesture) (Sussman *et al*., 1992). Thus, mastery of precise coordination of independent articulators may precede that of mechanically linked ones. Refinement of gestural organization and attainment of mature adult-like coarticulatory patterns may take several years (e.g., patterns of overlap in /r/V sequences change with increasing age, such as from 6 to 10 years, due to both perceptual and motor constraints).

Motor skill maturation may also be implicated in the temporal patterning of speech. Children speak more slowly than adults and with greater temporal variability. It is at approximately puberty that the temporal structure and organization of speech becomes adult-like. During this long time of development, changes do not simply involve temporal shortening of segments. More complex modifications are evident depending on a variety of factors (e.g., the sound involved and its context).

Prosodic Development

The acquisition of prosodic features constitutes a complex phenomenon requiring mastery of coordination between the respiratory, laryngeal, and supralaryngeal systems and relating output to linguistic structure and situational context in order to convey relevant grammatical, pragmatic, and affective information. Several prosodic features may be acquired early (e.g., adult-like intonation may appear in the late babbling period). However, refinement of prosodic features may occur over several years, leading to relatively comprehensive mastery of finer-grained aspects much later, at approximately puberty.

Some of the prosodic patterns that characterize infants' vocalizations during the first year of life include an increase in the duration of vocalizations, an increase in F0 range, and a predominance of F0 contours with a falling termination (Kent and Miolo, 1995). A first link between prosody and affective meaning may be assumed during the period of cooing vocalizations. Generally, pitch patterns in the early part of the first year may relate to physiological constraints and be associated with emotional expression; later developments from 9 months [0;9] to 2 years [2;0] involve associations between intonational patterns and meaning. At the end of the first year, receptive and expressive regression in prosodic patterns may indicate prosodic reorganization, marking a shift from a prelinguistic to a linguistic stage in prosodic development (Snow and Balog, 2002). A decline in the sensitivity of nonnative tonal contrasts occurs at 0;10–1;0. Regression in production can include infrequent use of falling contours despite their early acquisition. Such regression may also be attributed to articulatory constraints imposed by developments in segmental acquisition and early word production at the end of the first year.

Intonation

A biological bias toward the early acquisition of falling tones has been suggested. The predominance of falling contours can be attributed to biomechanical and aerodynamic factors (i.e., a decrease in subglottal pressure or a relaxation of the laryngeal muscles leading to less tense and shorter vocal folds toward the end of vocalizations). The later and more gradual development of rising tones has been attributed to greater physiological effort (i.e., tension or lengthening of the vocal cords and increase in subglottal pressure toward the end of vocalizations) or to the complexity of the linguistic functions performed by such contours in languages such as English. Acquisition of complex contours has been documented to occur last and show variability (Crystal, 1986; Snow and Ballog, 2002).

Cross-language data indicate that despite a possible physiological basis for the early development of falling tones, language experience plays a significant role in the developmental path of intonation already from the second half of the first year of life. Research on the acquisition of the falling tone by English-speaking chidren aged 1 and 4 years old has also shown that, similarly to adults, falling intonation by 4 year olds, but not 1 year olds, requires active speech production mechanisms and cannot be accounted for solely on the basis of physiological constraint models (Snow, 2004).

Although adult-like nuclear tones may appear as early as the late babbling period for some children, acquisition of basic nuclear tones and correct production of intonational contrasts generally appear when children start producing meaningful speech. Several studies have shown the use of an increasing number of contours by children aged 12 or 13 months (Crystal, 1986). During the single-word utterance stage, children can intentionally manipulate

intonation contours to signal different grammatical, attitudinal, and discourse meanings. For example, they can use falling vs. rising contours to express statements vs. requests by the age of 17 months. They can also use intonation to mark grammatical boundaries at 17 or 18 months of age. In general, grammatical use of intonation appears to coincide with the transition to syntax. Further advances in the comprehension and realization of intonational patterns appear to continue throughout childhood.

Stress and Rhythm

Further insights into the complex task of associating segmental and prosodic features have been obtained from research on stress. Although there is evidence of the use of appropriate acoustic parameters for stress marking in prelinguistic infants, significant developments in the acquisition of stress occur between 3 and 5 years of age and full establishment of the stress patterns of the ambient language does not occur until many years later, at approximately 12 years (Crystal, 1986).

Babbling infants from English-speaking environments can modulate relevant acoustic parameters (i.e., intensity, duration, and fundamental frequency) for stress marking (Davis *et al.*, 2000). However, control of stress in children's productions may not be fully established until some years later; for example, variability in stress marking has been reported for 2-year-olds but not 3- or 4-year-olds. Thus, development relates to increased stability in the production of stress. Evidence that 2-year-olds also produce unstressed syllables with significantly longer durations than older children and adults is in agreement with work by Allen and Hawkins (1980) that suggested that younger children encounter difficulties in reducing unstressed syllables (for a review of relevant studies, see Vihman, 1996). The development of the durational aspects supporting the stressed–unstressed contrast is relatively slow. Allen and Hawkins suggested that unstressed syllables in early words are overarticulated because they contain peripheral vowels and fully articulated consonants. In general, the absence of reduced syllables and the slower rate of speech produced by 2-year-olds result in the perception of a more syllable-timed rhythm. Although there is evidence of reduced syllables in the speech of 3-year-olds, variability has been reported in the proportion of accurately reduced syllables. Children achieve an increase in the rate of production and a higher number of reduced unstressed syllables producing more adult-like rhythmic patterns by the age of 4 or 5 years. Further developments, however, continue for some years and extend until late childhood.

The development of phonological rhythm has been associated with a tendency toward the establishment of a trochaic stress pattern in children's words. In support of this, evidence of a greater tendency for children to drop initial unstressed syllables in English and other languages has been reported. However, there is also influence from the predominant rhythmic pattern of the ambient language; for instance, use of iambic patterning (i.e., weak/strong stress pattern) has been reported for French infants at the 25-word stage. The fact that English-learning infants at the same stage also show variability in rhythmic patterns (probably due to competing models at the word and phrase levels; e.g., baby vs. a doll) suggests that further developments in the use of the trochaic pattern as a preferred frame in production may occur at the time of syntactic organization (Jusczyk, 1997).

Tone

There has been relatively limited research on the acquisition of tones; therefore, generalizations about the developmental course of tone perception and production need to be made with caution. More research has been carried out on Asian than African languages. On the basis of research findings during the past 35 years, some core observations can be made. Before 12 months of age, (i) infants can comprehend some of the linguistic uses of tone, and (ii) accurate production of tones precedes accurate production of segments. In addition, high tones are generally acquired earlier than low tones, whereas acquisition of lexical tones precedes acquisition of tone sandhi (see Crystal (1986), Vihman (1996), and Handford-Bernhardt and Stemberger (1998) for reviews of research studies). Evidence from Lao children between the ages of 3 and 15 years indicated that there were no errors on tones, although segmental errors persisted until 9 years of age. Data from Mandarin-speaking children at the one-word stage also showed correct reproduction of tones despite inaccuracies in the segmental content of the words. Evidence of earlier acquisition of nonrising tones in Mandarin has also been reported. Rapid acquisition of tones over a period ranging from 1;2 to 1;9 has been reported for one Cantonese-learning child. At the end of this period (1;10), tonal errors were rare but the segmental system was still undeveloped. Recent data from a large number of Cantonese-learning children showed that only 2 of 268 children between 2;0 and 5;11 made errors on tones. However, evidence of tonal errors at later ages (e.g., 4 years) has been reported for Latvian. Tonal sandhi rules may present problems until age 5 years and older. However, earlier acquisition of tone sandhi may occur in African languages, in

which tone is mainly grammatical and more tone sandhi exists (Handford-Bernhardt and Stemberger, 1998). Finally, evidence from a Sesotho-learning child indicates that acquisition of accurate tone marking varies for particular classes of morphemes (e.g., by age 2 years for subject markers and after 3 years for verb roots).

In general, earlier acquisition of tones compared to segments (mainly consonants) suggests that they are mastered with relative ease by children. Despite some similarities in the order of acquisition of tones among some languages, evidence of variability hinders general conclusions. Variability at different stages of tone acquisition can be due to individual differences among children, differences in language-specific tonal systems, the effect of tonal sandhi, and the interaction of tones with other aspects of the prosodic systems acquired (e.g., intonation and rhythm). Clearly, further cross-linguistic research is necessary for a comprehensive understanding of the acquisition of tones.

Conclusion

The development of speech presents the young learner with multiple challenges. To meet these, he or she enters the world with several genetically determined capacities, a bias toward language, the ability to learn, and the ability to use experience to shape development toward the ambient language. Early auditory sensitivity to speech sound contrasts and categorization abilities, biomechanical constraints, anatomical maturation of the auditory and speech production systems, neurological development and maturation of motor skills, an interaction between perceptual and production abilities, cognitive and linguistic development, experience with the ambient language, and development of social and emotional capabilities are some of the key parameters that play a significant role in the development of speech. Research during the past 30–40 years has provided important insights into the development of perceptual and production abilities of children. Many important questions remain to be addressed; toward this end, our understanding of the development of speech will benefit from greater research emphasis on the acquisition of different languages. In addition, further acoustic and articulatory studies, improved methodological designs, and advances in experimental techniques and data analysis will contribute significantly toward the discovery of spoken language. Many theoretical and methodological challenges toward comprehending the gift of speech in children remain.

Speech Errors as Evidence in Phonology

S A Frisch, University of South Florida, Tampa, FL, USA

Introduction

Speech error data have been used to argue for the psychological reality of many linguistic constituents (Fromkin, 1971; Stemberger, 1983; Dell, 1995). The most commonly occurring errors involve the units of phoneme, word, and morpheme. Speech errors also usually involve the interaction of two constituents in the utterance. For example, segmental errors frequently involve the confusion of onset segments between words (e.g., /sɛrɪŋ/ for 'getting' in 'getting such bad luck'). Interactions between constituents almost always involve two constituents of the same type (e.g., noun, syllable onset). Phonological speech error data focus on errors involving phonological constituents (e.g., segments, features) and prosodic positions (e.g., onset, nucleus, stress).

Speech error data are commonly collected in one of two ways. Spontaneous or naturally occurring speech errors are collected in normal communicative situations, such as everyday conversations or radio broadcasts. Experimentally elicited speech errors are collected under laboratory conditions and usually focus on creating segmental errors. There are two common procedures for eliciting segmental speech errors: the SLIPS technique and tongue twisters (see Baars *et al.*, 1975; Shattuck-Hufnagel, 1992). The SLIPS technique uses phonological priming to increase error rates (from <1% in normal speech to 5–10% in SLIPS). In the SLIPS procedure, a participant sees a series of word pairs containing the phonological contrasts of interest (e.g., /t/ and /k/ in tap cab, top cap, tall cave) and then sees a word pair that reverses the contrast (e.g., call take) and is cued to produce the reversal pair. Phonological tongue twisters also create speech errors at above normal rates (2–10%). Phonological tongue twisters typically use a four-word sequence that alternates a target contrast (e.g., top cap cop tab).

Speech Errors as Evidence for Phonological Structure

Both naturally occurring errors and experimentally elicited errors provide evidence for the prosodic

neurocognition: speech and face processing in the first year of life. Dordrecht, The Netherlands: Kluwer. 259–274.

Introduction

Speech error data have been used to argue for the psychological reality of many linguistic constituents (Fromkin, 1971; Stemberger, 1983; Dell, 1995). The most commonly occurring errors involve the units of phoneme, word, and morpheme. Speech errors also usually involve the interaction of two constituents in the utterance. For example, segmental errors frequently involve the confusion of onset segments between words (e.g., /sɛrɪŋ/ for 'getting' in 'getting such bad luck'). Interactions between constituents almost always involve two constituents of the same type (e.g., noun, syllable onset). Phonological speech error data focus on errors involving phonological constituents (e.g., segments, features) and prosodic positions (e.g., onset, nucleus, stress).

Speech error data are commonly collected in one of two ways. Spontaneous or naturally occurring speech errors are collected in normal communicative situations, such as everyday conversations or radio broadcasts. Experimentally elicited speech errors are collected under laboratory conditions and usually focus on creating segmental errors. There are two common procedures for eliciting segmental speech errors: the SLIPS technique and tongue twisters (see Baars *et al.*, 1975; Shattuck-Hufnagel, 1992). The SLIPS technique uses phonological priming to increase error rates (from <1% in normal speech to 5–10% in SLIPS). In the SLIPS procedure, a participant sees a series of word pairs containing the phonological contrasts of interest (e.g., /t/ and /k/ in tap cab, top cap, tall cave) and then sees a word pair that reverses the contrast (e.g., call take) and is cued to produce the reversal pair. Phonological tongue twisters also create speech errors at above normal rates (2–10%). Phonological tongue twisters typically use a four-word sequence that alternates a target contrast (e.g., top cap cop tab).

Speech Errors as Evidence for Phonological Structure

Both naturally occurring errors and experimentally elicited errors provide evidence for the prosodic

structures of phonological representation proposed by phonologists. Evidence for the influence of phonological features on speech errors comes from the fact that errors between segments that are similar (and thus share many phonological features) are more common than errors between segments that share fewer phonological features (van den Broeke and Goldstein, 1980). Evidence for features can also be found, though rarely, in speech errors that appear to involve the rearrangement of individual phonological features. Fromkin (1971) presents the error /glir plu/ for 'clear blue' as an error involving [voice] only.

Analogous errors occur that involve the rearrangement of a single segment, syllable onset, syllable rime, and whole syllable (Fromkin, 1971). For example, the error /frɪʃ gɑto/ for 'fish grotto' involves the misproduction of a single segment constituent, distinct from the syllable onset constituent. Complex syllable onsets can also act as a unit in speech errors, as in /ske pel/ for 'pay scale.' Among naturally occurring phonological errors, where the probabilities of different error types have been examined, the most common errors involve a single phoneme. Errors involving whole syllables or subsyllabic constituents are less common.

Speech Errors as Evidence for Phonological Constraints

Interactions between segments in speech errors largely happen between segments in identical position within the word, syllable, and prosodic structure. For example, Shattuck-Hufnagel (1992) found that errors were most likely between segments that shared word onset position and stress. She used tongue twisters that were specially constructed to vary stress and position in the word between similar segments. For example, the tongue twister 'parade fad foot patrol' put the similar pair /p, f/ in shared word initial position, but different stress position. Shattuck-Hufnagel (1992) found errors were less frequent when the segments were not both word onsets (e.g., word onset and a word medial syllable onset). Errors were also less frequent with a difference in syllable stress (e.g., word onset in a stressed syllable and word onset in an unstressed syllable, as in 'parade fad foot patrol').

It has also been claimed that speech errors respect the phonological/phonotactic patterns of the language. For example, in the error /tæp stɑbz/ for 'tab stops,' the exchange of /p/ with /b/ also changes the voicing of the plural morpheme, as required by English phonology. Dell *et al.* (2000) systematically examined phonological constraints on speech errors using tongue twisters. They found that facts of language phonotactics, such as /h/ only appears as a syllable onset in English, are rarely violated in elicited speech errors. Errors that changed the prosodic position within the syllable of other segments occurred much more frequently. (For example, /f/ or /s/, which can be either an onset or a coda in English, changed from onset to coda in an error much more frequently than /h/. In addition to true phonotactic constraints from English, Dell *et al.* (2000) also examined artificial phonotactic constraints that existed only within the context of the experiment (e.g., /ʃ/ only ever appears as an onset in the words used in the experiment). Dell *et al.* (2000) found that in these experiments, the experiment specific, artificial phonotactic constraints were also infrequently violated. Since errors in general usually preserve the within-syllable position of the error segment, Dell *et al.* (2000) hypothesize that the mechanisms that maintain syllable position in speech errors are the same mechanisms that prevent errors that create phonotactically illegal sequences. Since phonotactic constraints are always present in the use of language, they have a strong effect on speech error outcomes. Less robust phonotactic generalizations, like ones within a set of experiment stimuli or within a single stimulus item (such as '/s/ is a syllable onset in this word'), have a weaker effect on speech error outcomes.

Cross-Linguistic Speech Errors

While most of the research on phonological speech errors has used English-language data, some studies have explored how cross-linguistic differences influence speech errors. For example, evidence for the psychological reality of the Arabic root-and-pattern morphological structure has been found. Speech errors by Arabic speakers rearrange the segments within a root morpheme far more frequently than speech errors by English speakers or German speakers rearrange the segments within a word (Berg and Abd-El-Jawad, 1996). For example, a Jordanian Arabic speaker's production of /milih/ when the intended word was /hilim/ 'dream' contains a word internal rearrangement of consonants in the root morpheme. Interestingly, this error also changes the prosodic position of the consonants (by switching an onset with a coda). Word-internal segment rearrangement errors like this in Arabic are less sensitive to syllable structure constraints than errors that rearrange segments between two different words. For between-word errors, Arabic is similar to English in respecting prosodic position. This suggests that word-internal root consonant rearrangement errors in Arabic apply at the consonantal root level of representation, which is a level that is specific to the morphology of root-and-pattern languages.

Chen (2000) examined speech errors in Chinese. The phonological inventory of Chinese is much more limited than English, which reduces the need for subsyllabic units in the analysis of Chinese. As a result, it may be that Chinese speakers utilize syllable-sized chunks in processing. Syllable-sized chunks are also reflected in the Chinese writing system. Thus, syllable unit errors are likely to be more frequent in Chinese than in English. Chen (2000) found that syllable errors do occur relatively frequently in Chinese, and at a rate that is higher than predicted from analyzing syllable errors as errors involving multiple subsyllabic units.

The Validity of Speech Error Data

All of the phonological speech error data discussed thus far was collected using phonetic transcription. Phonetic transcription is limited as a research tool in many ways. The transcription system itself is inherently segmentally based, and transcription depends on the perception of the listener (Boucher, 1994). Thus, the apparent abstractness of phonological speech errors may follow from perceptual biases in the listener rather than real abstractness in the data. Recent research has begun to address this issue by examining speech errors instrumentally, using the tools of phonetics.

Mowrey and MacKay (1990) examined muscle fiber activation in the production of tongue twisters and found a wide range of variation in production. Aberrant muscle activations were found that were appropriate for the normal production of an incorrect segment. However, much smaller aberrant muscle activations were also found, suggesting that partial or gradient errors frequently occurred. These gradient errors were frequently imperceptible to the experimenters.

Frisch and Wright (2002) conducted an acoustic study of voicing errors in fricatives. They found cases of partial voicing or devoicing of fricatives. They also found a systematic bias in their perception of fricative voicing errors. Almost any amount of voicing of a fricative resulted in the percept of a voiced fricative, while complete voicelessness was required to get a perception of a voiceless fricative. Thus, a transcription-based study of speech errors would have concluded that errors from a voiceless fricative to a voiced fricative were much more common than the reverse, even though that was not true acoustically.

Pouplier (2003) examined speech articulation during the production of speech errors using electromagnetic midsagital articulometry (EMA) to track tongue movement. Pouplier found that many errors cannot be explained as the rearrangement of abstract phonological constituents. Many errors were found that reflected partial activation of gestures, resulting in incomplete movement of an articulator that was imperceptible to listeners. These errors also often resulted in gestural sequences that were abnormal, and thus phonotactically illegal.

Together, these instrumental studies of speech errors call into question the validity of speech error evidence as evidence for traditional notions of phonological constituents and constraints as nonquantitative, abstract symbols governed by inviolable rules. However, speech error evidence is not unique in this regard. Research in other domains of phonetics and phonology has also found that phonological competence may be quantative and grounded in less abstract phonetic categories. This suggests that speech error data will continue to provide converging evidence for the structure and organization of the phonological system within and across languages.

Introduction

Natural speech is far from perfect: it is replete with filled and unfilled hesitations and errors. A speech error is a mismatch between what we intend to say and what we actually say. This article focuses upon mismatches involving the sounds of the language, called slips of the tongue, and will not cover hesitations in speech. Speech errors made by nonbrain-damaged speakers resemble the errors made by speakers with brain damage, and the study of both sorts of error has revealed a great deal about how humans produce language, and about the relation between language and the brain. This article focuses on the speech of nonbrain-damaged speakers.

Classification of Speech Errors

Speech errors can be classified according to the units of processing and types of mechanism involved.

The units involved in slips of the tongue range from phrases, through words (e.g., saying 'pass the **pepper**' instead of 'pass the salt'), morphemes, and phonemes (e.g., saying '**fl**ock of **b**ats' instead of 'block of flats'), to features (e.g., saying 'turn the kno**p**' instead of 'knob'). Mechanisms include anticipations (e.g., saying 'the **m**irst of May' instead of 'the first'), perseverations (e.g., saying 'God rest **r**e merry gentlemen' instead of 'God rest ye'), exchanges (e.g., 'Guess whose **mind** came to **name**?' instead of 'name came to mind'), substitutions ('Get me a **fork**' instead of 'knife'), and blends (saying 'chung' for 'children' and 'young').

Two particular types of speech error deserve special mention. Spoonerisms are errors where the initial consonants of words have exchanged. They are named after the Reverend Dr William Archibald Spooner (1844–1930), Warden of New College, Oxford, who was particularly prone to making this sort of error (and indeed, may have suffered from a mild developmental language disorder). Some examples of alleged errors made by Dr Spooner are:

(1) You have wasted the whole term → You have **t**asted the whole **w**orm.

(2) The Lord is a loving shepherd to his flock → The Lord is a **sh**oving **l**eopard to his flock.

Note that in both of these examples the error strings produced form words; these errors are therefore possible instances of the lexical bias effect described below.

Malapropisms are named after Mrs Malaprop, a character in Richard Brinsley Sheridan's play *The Rivals*. Mrs Malaprop often used grand words incorrectly, such as saying 'epitaphs' for 'epithets' and 'reprehend' for 'apprehend.' Following Fay and Cutler (1977), the term has been used for all phonological word substitutions that inadvertently arise from processing difficulty, rather than ignorance, such as:

(3) Liszt's Hungarian Rhapsody → Liszt's Hungarian **restaurant**

Methodology of Speech Error Collection

There are two main techniques for collecting speech errors. The first method involves recorders noting speech errors they observe in everyday life. This methodology has two advantages. First, it is

Some examples of alleged errors made by Dr Spooner are:

(1) You have wasted the whole term → You have **t**asted the whole **w**orm.

(2) The Lord is a loving shepherd to his flock → The Lord is a **sh**oving **l**eopard to his flock.

Note that in both of these examples the error strings produced form words; these errors are therefore possible instances of the lexical bias effect described below.

Malapropisms are named after Mrs Malaprop, a character in Richard Brinsley Sheridan's play *The Rivals*. Mrs Malaprop often used grand words incorrectly, such as saying 'epitaphs' for 'epithets' and 'reprehend' for 'apprehend.' Following Fay and Cutler (1977), the term has been used for all phonological word substitutions that inadvertently arise from processing difficulty, rather than ignorance, such as:

(3) Liszt's Hungarian Rhapsody → Liszt's Hungarian **restaurant**

Methodology of Speech Error Collection

There are two main techniques for collecting speech errors. The first method involves recorders noting speech errors they observe in everyday life. This methodology has two advantages. First, it is

naturalistic. Second, it enables a comprehensive corpus of all types of error to be built up. The disadvantage of this technique it is that is prone to bias. Observers may be more likely to observe certain types of error (e.g., sound-level errors might be less noticeable than word-level errors), and they may also be less likely to remember and record certain types of error.

The second method of collecting errors, laboratory-based induction, involves the presentation of words on a display device (now a computer screen, previously a memory drum) with the participant's task usually being to name word pairs as rapidly as possible. The participant makes an error on a small proportion of errors (e.g., reading BARN DOOR as 'darn bore'). The advantages of this methodology are that it is easy to collect a relatively large number of errors of the sort the experimenter is interested in (here spoonerisms), and that it is possible to have some element of control over the errors made. The disadvantages are that the technique is more intrusive, the errors involve some element of reading, and the types of error that can be observed are restricted.

Fortunately, the evidence provided by these methods is convergent. Analysis of recorded speech suggests that observer bias effects are not large, although they obviously remain a concern.

Interpretation of Speech Errors

Speech production comprises conceptualization, formulation, and encoding (Levelt, 1989). Conceptualization involves determining what to say – we create the message. Formulation involves translating the message into a linguistic form, and has two aspects: syntactic planning and lexicalization (the process whereby word concepts are turned into sounds). Finally, execution involves detailed phonetic and articulatory planning. Speech errors have informed our understanding of all of these stages.

It is important to note that the occurrence of slips of the tongue is not random. In particular, some sorts of errors that could occur do not (e.g., we do not observe function words exchanging with content words). This order is the basis for explaining how and why errors arise in terms of a model of speech production. The basic idea is that for an error to occur, the two elements of the error (intended and actual outcome) must be simultaneously active at the same level of processing. For example, words exchange with words, but content words only exchange with other content words, and function words with other function words; content words do not exchange with function words, or vice versa. This finding is extraordinarily robust: in my corpus of several thousand speech errors, there is not a single instance of a content word exchanging with a function word. This observation supports the idea that content and function words are from computationally distinct vocabularies that are accessed at different levels of processing.

There are also very different constraints on word and sound exchange errors. Sounds only exchange across small distances, whereas words can exchange across phrases; words that exchange tend to come from the same syntactic class, whereas sound exchange errors are not constrained in this way, but instead swap with words regardless of their syntactic class.

Syntactic Planning

The extension of this type of argument led to the development of the standard, or the Fromkin–Garrett, model of speech production. Consider the following famous example from Fromkin (1971, 1973):

(4) a *weekend* for MANIACs → a *maniac* for WEEKENDs

The capital letters indicate the primary sentence stress and the italics secondary stress. The error left the stress unchanged, suggesting that stress is generated independently of the particular words involved. Note also that the plural morpheme '-s' remained where it was originally intended to be: it did not move with 'maniac,' but instead was stranded. Furthermore, the plural morpheme was realized as /z/, not /s/, so that the plural ending sounds consistent with the word that actually came before it, not with the word that was originally intended to come before it. This error is an example of accommodation to the phonological environment.

In Garrett's model (**Figure 1**) there are two major stages of syntactic planning. At the earlier functional level, word order is not explicitly represented. The semantic content of words is specified and assigned to roles such as subject and object. At the positional level, words are explicitly ordered. There is a dissociation between syntactic planning and lexical retrieval. There is a further dissociation within lexical retrieval: Garrett argued that content and function words play very different roles in language production, with content words being selected at the functional level, whereas function words are not selected until the positional level.

In this model, word exchanges occur at the functional level. As only the functional roles of the words and not their absolute positions are specified at this level, word exchanges are constrained by syntactic

Figure 1 Garrett's model of speech production.

category but not by the distance between the exchanging words. Next we generate a syntactic frame for the planned sentence. The phonological representations of content words are then accessed from the lexicon using the semantic representation. Content words are then inserted into the syntactic planning frame, where final positions are specified to form the positional level. The function words and other grammatical elements are then phonologically specified to give the sound-level representation. Sound exchanges occur at this stage and, as their absolute position is now specified, such errors are constrained by distance.

Garrett's model accounts for a great deal of the speech error evidence, but a number of subsequent observations suggested that some aspects of it might not be correct. First, it is not at all clear that speech production is strictly serial. There is clearly some evidence for at least local parallel processing in word blend errors, which must be explained by two (or more) words being simultaneously retrieved from the lexicon, as in (5). More problematically, we find blends of phrases and sentences (e.g., [6]). Furthermore, the locus of these blends is determined phonologically, so that the two phrases cross over where they are most similar in sound, suggesting that the alternative messages are processed in parallel from the message to the sound levels (Butterworth, 1983).

We also observe cognitive intrusion errors where material extraneous to the utterance intrudes into it. The message level can intrude into lower levels of processing, producing nonplan-internal errors (e.g., [7]). These errors are often phonologically facilitated, meaning that they are more likely to occur if the target word and intrusion sound alike (Harley, 1984). The names of objects or words in the outside environment can also intrude into speech, producing environmental contamination errors (e.g., [8]). Once again we find that phonological facilitation of environmental contaminants occurs more often than one would expect by chance (although to a lesser degree than with other cognitive intrusions).

(5) Utterance: It's difficult to **valify**. (Targets: validate + verify)

(6) Utterance: I'm **making the kettle on**. (Target 1: I'm making some tea. + Target 2: I'm putting the kettle on.)

(7) Utterance: Have you got your **key** in? (Target: Have you got your car in? Context: The speaker reported that he had considered adding why he wanted to know whether the other person had their car in – because the speaker wanted a lift to fetch the key.)

(8) Utterance: Get out of the **clark**. (Target: Get out of the car. Context: The speaker was looking at a shop front in the background that had the name 'Clark's' printed on it. The speaker reported that he was not aware of this at the time of speaking.)

Lexical Access

There is an emerging consensus that lexicalization is a two-stage process. When we produce a word, processing moves from the semantic level to an intermediate level containing lemmas, which are specified syntactically and semantically. We then retrieve the phonological forms of these words in a stage of phonological encoding. There is a great deal of evidence supporting the two-stage hypothesis.

Fay and Cutler (1977) observed that there were two distinct types of whole-word substitution speech error: semantic substitutions, such as (9) and (10), and form-based substitutions, such as (11) and (12):

(9) fingers → **toes**

(10) husband → **wife**

(11) equivalent → **equivocal**

(12) historical → **hysterical**

Fay and Cutler argued that the existence of two types of word substitution suggests that the processes of word production and comprehension use the same lexicon, but in opposite directions. Items in the lexicon are arranged phonologically for spoken word recognition, so that words that sound similar are

close together. The lexicon is accessed in production by traversing a semantic network. Semantic errors occur when traversing the decision tree, and phonological errors occur when the final phonological form is selected. Although the idea that lexicalization occurs in two stages appears to be supported by evidence from other sources such as picture naming, tip-of-the-tongue states, studies of people with anomia, and brain imaging, there is nevertheless some dissent (Caramazza, 1997; Caramazza and Miozzo, 1997).

Feedback in Speech Production

Is there reverse information flow when we choose words? Models based primarily on speech error data see speech production primarily as an interactive process involving feedback (e.g., Dell, 1986; Dell and Reich, 1981; Harley, 1984; Stemberger, 1985) because speech errors show evidence of multiple constraints, called familiarity biases and similarity effects.

Familiarity bias is the tendency for errors to produce familiar sequences of phonemes. In particular, lexical bias is the tendency for sound-level speech errors such as spoonerisms to result in words rather than nonwords (e.g., 'barn door' being produced as 'darn bore') more often than chance would predict. Although we would expect some sound errors to form words sometimes by chance, Dell and Reich showed that this happens far more often than is expected by chance. This interaction between lexical and phonological processes has been shown both for naturally occurring speech errors (Dell, 1986; Dell and Reich, 1981) and in artificially induced spoonerisms (Baars *et al.*, 1975). Some aphasic speakers show lexical bias in their errors (Blanken, 1998).

Similarity effects arise when the error is more similar to the target than would be expected by chance. In mixed substitution errors the intrusion is both semantically and phonologically related to the target (e.g., [13] and [14]). We find mixed errors far more often than would be expected by chance alone (Dell and Reich, 1981; Harley, 1984; Shallice and McGill, 1978). We also find similar results in artificially induced speech errors (e.g., Baars *et al.*, 1975; Motley and Baars, 1976) and in errors arising in complex naming tasks (Martin *et al.*, 1989).

(13) comma → **colon**

(14) calendar → **catalogue**

Similarity effects are problematical for serial models such as Fay and Cutler's. The basic model must be modified in one of two ways. Butterworth (1983) proposed that a filter or editor checks the output to see that it is plausible; it is less likely to detect an error if the word output sounds like the target should have been, or is related in meaning. Such a mechanism, although it might be related to comprehension processes, is not considered to be parsimonious.

There is instead an emerging consensus among speech production theorists that lexicalization can be described by spreading activation in an interactive activation model. Dell (1986), Harley (1993), and Stemberger (1985) proposed different versions of the same basic model.

Dell's Interactive Model of Speech Production

Dell (1986) proposed an interactive model of lexicalization based on the mechanism of spreading activation. Items are slotted into frames at each level of processing. Processing units specify the syntactic, morphological, and phonological properties of words. Activation spreads from the sentence level, where items are coded for syntactic properties, through a morphological level, to a phonological level. At each level, the most highly activated item is inserted into the currently active slot in the frame. The flow of activation throughout the network is time dependent, so that the first noun in a sentence is activated before the second noun. Feedback between the phonological and lexical levels gives rise to lexical bias and similarity constraints.

The model gives a good account of the origin of word- and sound-level errors. Several units may be active at each level of representation at any one time. If there is sufficient random noise, an item might be substituted for another one. As items are coded for syntactic category and position, the other units that are active at any one time tend to be similar to the target in these respects.

The Tip-of-the-Tongue State

The failure to produce at all is the ultimate speech error. A tip-of-the-tongue (TOT) state is a noticeable temporary failure of lexical access, where the word can take some considerable time to be produced, if it is at all. In a TOT state, you know you know the word, but cannot access the sounds.

Brown and McNeill (1966) were the first to examine the TOT state experimentally. They induced TOTs by reading people definitions of low-frequency words (e.g., [15], which defines 'sextant'):

(15) 'A navigational instrument used in measuring angular distances, especially the altitude of the sun, moon, and stars at sea.'

Brown and McNeill found that a sizable proportion of people will be placed in a TOT state by this task. Furthermore, in a TOT, partial information about the target word, such as the number of syllables, the initial letter or sound, and the stress pattern, can sometimes be retrieved. People also sometimes produce near phonological neighbors such as 'secant,' 'sextet,' and 'sexton'; these other words that come to mind are called interlopers.

The tip-of-the-tongue state is readily explained as success of the first stage of lexicalization but failure of the second stage. In support of this idea, Vigliocco *et al.* (1997) showed that grammatical gender can be preserved in TOT states in Italian. That is, even though speakers cannot retrieve the phonological form of a word, they can retrieve some syntactic information about it. Two theories have been proposed to explain why the second stage of lexical access fails in TOTs. Brown and McNeill (1966) proposed the partial activation hypothesis, which states that the target items are inaccessible because they are only weakly represented in the system. Burke *et al.* (1991) provided evidence in favor of this model from experimental and diary studies. They argued that the retrieval deficit involves weak links between the semantic and phonological systems. The blocking hypothesis, first proposed by Woodworth (1938), states that the target item is actively suppressed by a stronger competitor. Jones and Langford (1987) used a variant of the Brown and McNeill task known as phonological blocking to test this idea. They presented a phonological neighbor of the target word and showed that the presence of this neighbor increases the chance of a TOT state occurring, whereas presenting a semantic neighbor does not. They interpreted this as showing that TOTs primarily arise as a result of competition. However, the same pattern of results is found with these materials when the blockers are not presented, suggesting that the original results were an artifact of the materials (Perfect and Hanley, 1992; Meyer and Bock, 1992).

Harley and Bown (1998) showed that TOTs are more likely to arise on low-frequency words that have few close phonological neighbors. This finding fits a partial activation model of the origin of TOTs rather than an interference model. Indeed, phonological neighbors appear to play a supporting rather than a blocking role in lexical access. So far, then, the TOT data best support the partial activation hypothesis.

The Freudian Slip

Freud argued that slips of the tongue are "a window to the mind" in that they provide insight into the hidden, repressed desires and opinions of speakers. In part of a general treatise on action slips, or parapraxes, Freud (1975) noted the occurrence of slips of the tongue, and proposed that they revealed our repressed thoughts. In one of his examples, a professor said in a lecture, "In the case of female genitals, in spite of many *Versuchungen* [temptations] – I beg your pardon, *Versuche* [experiments]…." Not all Freudian slips need arise from a repressed sexual thought. In another example he gives, the President of the Lower House of the Austrian Parliament opened a meeting with "Gentlemen, I take notice that a full quorum of members is present and herewith declare the sitting closed [instead of open]!" Freud interpreted this as revealing the president's true thoughts, which were that he secretly wished a potentially troublesome meeting closed. Such errors have come to be known as Freudian slips. Ellis (1980) reanalyzed Freud's collection of speech errors in terms of a modern process-oriented account of speech production. The problem with the Freudian interpretation is that most (if not all) of the examples he provides are more simply accounted for in terms of the simple cognitive mechanisms described above. There is no need to invoke complex motivational systems as well. Nevertheless, a small number of errors might be true Freudian slips. It is certainly the case that thoughts can intrude into overt speech, as is shown by the following example (16) from Harley (1984):

(16) Utterance: I've **eaten** all my library books.
(Target: I've read all my library books. Context: The speaker was hungry and thinking of getting something to eat.)

Speech Genres in Cultural Practice

R Bauman, Indiana University, Bloomington, IN, USA

Foundations

The beginnings of a systematic discrimination among speech genres may be traced to the efforts of Jacob and Wilhelm Grimm in framing their great collections of German oral narrative. In the introductions to their various works on *Märchen*, legends, and mythology, the Grimms delineated a relational series of narrative genres based on the correspondence of the respective genres to 'real life' and actual people, places, and events, expressive tone, and the modes of cognitive, affective, and interpretive engagement each type elicits from its audiences. Owing to the pioneering nature of their work, their scholarly credentials, and the great popularity of their collections, the Grimms' threefold distinction of fairy tale, legend, and myth attained a canonical status among students of oral narrative that persists to this day (Grimm, 1844; Grimm and Grimm, 1816–1818).

The Grimms' classificatory efforts may be seen as an early manifestation of the scientizing of philology, of which Jacob especially was an ardent advocate. As folklore likewise came to aspire to scientific status, classification became one of the hallmarks of methodological rigor. Building upon the Grimms' model and the burgeoning of scientism more generally, classification assumed a central place in folklore, commonly as part of a three-phase program consisting of collection, classification, and analysis. Analysis amounted largely to the study of textual histories, based upon the systematic comparison of variants and versions of particular folklore items. Accordingly, the preponderance of efforts devoted to classification were in the service of such genetic, text-historical research.

Vladimir Propp offered his seminal work of genre definition, *The morphology of the folktale* (1928) as a critical corrective to prevailing approaches to classification in folklore. Propp was a vigorous advocate of the importance of classification to scientific study but dismissive of the classificatory efforts of the philological folklorists. Consistent with the Russian Formalist commitment to exact description (or specification) of literary phenomena on formal, constructional grounds – how is it made? – and to plot (*sjuzhet*) as the formal arrangement of constituent elements, Propp advanced a definition of the Russian magic tale in terms of the underlying plot structure that was constitutive of the genre. The constituent elements were the functions – actions, functionally defined – of the *dramatis personae*. The definitional model consisted of a syntagmatic structure of 31 functions, each defined by its place in the sequence. Certain functions were obligatory, others optional, and the model allowed for the recursive repetition of certain plot sequences. For political and linguistic reasons, Propp's work was inaccessible to Western scholars for three decades, but with the publication of an English translation in 1958 (revised in 1968), it quickly became a charter document for scholars in a number of disciplines (including linguistics, anthropology, and folklore), generating widespread interest in the formal definition and analysis of oral genres.

Generic problems (though not the term), played a certain operational role in the Americanist tradition of Boas and his intellectual heirs, though the concept was seldom the focus of critical examination in their work. Given the centrality of texts in the Boasian tradition, rooted in the philological foundations of Boasian anthropology, discriminations among orders of texts was at times seen to be a necessary task, at least for certain purposes. In general, however, Boas was distrustful of generic distinctions. In his comparative investigations of the narrative repertoires of

North American peoples, Boas discovered that particular themes and motifs might diffuse with some degree of independence, to combine and recombine with other elements in a variety of shifting ways. In larger scope, by whatever criteria one might employ to make generic distinctions between myth and folktale for example, Boas perceived that there is "a continual flow of material from mythology to folktale and *vice versa*" (1940: 405). Boas's distrust of various attempts to discriminate between narrative genres was further bolstered by his perception that such distinctions did not remain consistent for specific narratives across cultural boundaries; once again, by whatever criteria the distinction was attempted, narratives that were clearly genetically related might appear in one group's repertoire to belong to one class and in the neighboring group's repertoire to another. Hence, Boas attributed the "somewhat indefinite" use of the terms 'myth' and 'folk-tale' to "a lack of a sharp line of demarcation between these two classes of tales" (1940: 454).

There is, however, one basis for discriminating between myths and folktales to which Boas is prepared to accord a degree of legitimacy and productiveness – this is a distinction purportedly "given by the Indian himself," between two types of tales, one that relates events that happened during a formative period in the history of the world, namely, myths, and a second that relates events set in "our modern period," that is to say, history (1940: 454–455). Concerning this purportedly native-based distinction, Boas reminds us that here too historical and comparative investigation reveals movement between the two categories and that, from his analytical point of view, this way of sorting out narrative genres is no better founded than those devised by scholars. It does, however, have the advantage of corresponding "to concepts that are perfectly clear in the native mind," a critical corrective to *a priori* and ethnocentric discriminations.

The most prominent use of generic distinctions in the Boasian tradition occurs in the organization of text collections. Perusal of these collections, however, reveals that the grouping of texts within their pages is frequently quite *ad hoc*, without discussion of the conceptual basis of the respective sections. The distinction between myths and tales/historical narratives attributed by Boas to North American cultures generally has some shaping effect on text collections, but other sorting principles such as grouping by informant may also be found.

In British social anthropology, which was little influenced by the philological tradition that shaped Americanist anthropology, genre figured not at all, with the important exception of Bronislaw Malinowski's writings on the culture of language in the Trobriand Islands. Malinowski's effort in 'Myth in primitive psychology' (1948: 101–108) to organize his treatment of Trobriand narrative in terms of "the natives' own classification and nomenclature" marks a pioneering departure from inherited perspectives on genre. Malinowski, as is well known, discovered a tripartite system of narrative types among the Trobrianders: (1) *kukwanebu*, individually owned, told for entertainment in sociable occasions and for encouraging the growth of recently planted gardens, formally marked by a 'short ditty' at the end, and enhanced in the telling by performance elements such as special voice qualities, mimicry, and audience response; (2) *libwogwo*, not confined to a specific season, regarded as true, dealing with subjects of intense interest concerning actions and events redounding to the credit of an individual, lineage, or community; and (3) *liliu*, sacred narratives that come into play when a rite, ceremony, or social or moral rule demands justification, the warrant of antiquity, reality, and sanctity, and believed to recount the real cause that has brought about the moral rule, social grouping, custom, or rite in question.

Malinowski insists that an ethnographically valid description must take as much account of contextual factors – both cultural and situational – as textual ones: "The stories live in native life and not on paper, and when a scholar jots them down without being able to evoke the atmosphere in which they flourish he has given us but a mutilated bit of reality" (1948: 104). Still further, the understanding of any class of narratives demands attention to its place in the overall system of narrative genres. This principle is what motivates his elucidation of all three classes of Trobriand narrative as a prolegomenon to the analysis of myth. In the face of Malinowski's ethnographic contextualism, however, it is a testimony to the enduring power of the Grimms' classic typology that he assimilates the Trobriand genres to the three canonical forms they identified by glossing *kukwanebu* as 'fairy tales', *libwogwo* as 'legends' (though also as 'historical accounts' and 'hearsay tales'), and *liliu* as 'myths'.

Conceptions of Genre

Etic Versus Emic Perspectives

Boas's interest in generic distinctions that are salient "in the mind of the American native," "given by the Indian himself," and Malinowski's pioneering account of Trobriand narrative genres, elucidated in terms of locally defined and named categories, adumbrate a relativist, ethnographic orientation to genre

and genre systems as to be discovered. This focus on indigenous distinctions, expressed in native terms, contrasts significantly with approaches to genre definition that view it as an essentially analytical, classificatory operation, the province of scholars, of little conscious interest to the people who produce the generically regimented discourse. The direction pointed by Boas and Malinowski were not widely or systematically pursued until the late 1960s and 1970s (Ben-Amos, 1976), stimulated by an upsurge of interest in classification as an ethnographic problem and in ethnographic perspectives on language in society and culture. Indigenous systems of classification represented a significant focus of structuralism and also of ethnoscience, guided by a reorientation from etic to emic perspectives in the study of culture and by the analytical rigor of structural-semantic analysis. And genre was from the beginning a key concept in the development of the ethnography of speaking, viewed as a nexus of interrelationships among the constituents of the speech event and as an organizing framework for speaking practice.

Perhaps the most comprehensive and methodologically influential study of an indigenous genre system was Gary Gossen's analysis of Chamula genres of verbal behavior, which combined the perspectives of ethnoscience, structuralism, and the ethnography of speaking (Gossen, 1972). Gossen's study is exemplary in its systemic and comprehensive scope, its close attention to Chamula Tzotzil terms and glosses, and its correlation of the Chamula speech genres with other aspects of society and culture (Figure 1).

The domain of people's speech (*sk'op kirsano*) includes three general types of speech: ordinary speech (*loʔil k'op*), speech for people whose hearts are heated (*k'op sventa šk'išnah yoʔnton yuʔun li kirsano*) and pure (or true) speech (*puru k'op*). These supercategories, in turn subsume a range of speech genres, as illustrated in the accompanying figure. The taxonomy has a number of systemic organizing principles. As we move, for example, from ordinary speech to speech for people whose hearts are heated to pure speech, the genres are marked by increasing formal elaboration (repetition, parallelism, metaphorical couplets), redundancy, and invariance, with the genres of pure speech – and especially ancient words – constrained by an ideology of fixity and

Figure 1 Chamula genres of verbal behavior, with permission from The American Folklore Society.

authoritativeness. These gradient features are all indices of increasing heat, the energizing force of the Chamula cosmos, deriving from Our Father the Sun. Heat, in Chamula culture, is a metaphor for power, control, order, weightiness. It is correlated with the life cycle, in which an individual accrues heat in the process development from babyhood to full, mature adulthood, and with gender, with men having more heat than women.

The simple parallel structures of children's improvised games both expresses and indexes their increasing heat, and prepares them for the mastery of still more heated and formally elaborated genres as they mature into adulthood. Only the most potently mature and ritually able men can perform the most heated genres of ancient words. The full range of social and cultural correlatives of Chamula genres extends well beyond these few dimensions, suggesting how the ethnographic elucidation of a genre system in culture-specific terms may serve as a revealing vantage point on society and culture more generally.

Not all cultures, to be sure, exhibit as high a degree of metapragmatic awareness as the Chamula, for whom 'people's speech' is a cultural focus. Ethnographic research has made clear that there is a great deal of variability both across and within speech communities with regard to the naming and recognition of speech genres and the organization and coherence of genre systems. The taxonomy that Gossen elicited from his Chamula consultants represents only those categories and relationships on which consultants agreed; other named genres escaped that consensus. And once we reach the fuzzy fringes of generic coherence, at the point where the orderliness of a genre system begins to unravel, we face the question of just how much of a community's speech economy is generically encompassed. Some scholars, including Bakhtin, insist that there is no utterance that is not organized by genre, while others find it more productive to restrict the aegis of genre to named and generally recognized discursive forms (see 'Genre in Context' below).

Ontology and Epistemology of Genre

One of the most widely employed and durable criteria for defining and discriminating among genres is the ontology and epistemology of the worlds they represent. The Grimms, for example, distinguished between narratives that are set in the "perceivable and conceivable natural world" from those that mirror forth an "incredible, uncanny world." In a similar vein, Boas, posited as "perfectly clear" in the minds of Native Americans a distinction between narratives recounting conditions and events that occurred during a formative point in the history of the world, that is, myths, and narratives that are set in the contemporary world, namely, history. There are many cases in the ethnographic record of locally defined genre distinctions based on like ontological and epistemological distinctions.

The positing of such categorical distinctions as "perfectly clear," however, should not be allowed to obscure those situations in which the ontology of the represented world is blurred, ambiguous, or contested. Indeed, the ambiguation of the represented world may serve as an expressive resource. The tall-tale, for example, depends for its effect on the gradual dislocation of ontological and epistemological expectations, appearing initially to be set in the real world, but carried by its narrative trajectory toward a world of hyperbolic unreality. Or, a given genre may serve as an expressive vehicle for epistemological contemplation and debate. Some considerations of legend, for example, suggest that this genre is more about problematizing categorical epistemological distinctions between the natural world and the uncanny world than about resolving them, a forum for epistemological speculation rather than resolution.

Matters of generic ontology and epistemology have attracted renewed interest among contemporary scholars, stimulated by Bakhtin's notion of chronotope (Bakhtin, 1986: 42), literally 'time-space,' the configuration and interrelationships of time and space that distinguishes – indeed, Bakhtin suggests at times, defines – genres. Recall the Chamula genre system, discussed in the preceding section, in which there is a macro-level distinction between new (or recent) words (*ʔač' k'opetik*), associated with "close time-space coordinates and the Fourth Creation," and ancient words (*ʔantivo k'opetik*), associated with "distant time-space coordinates and the First, Second, or Third creations."

The concept of chronotope is suggestive on a number of grounds. While most considerations of the ontology and epistemology of genres – including some of Bakhtin's own – center on narrative genres, Bakhtin extends the perspective to all speech genres, suggesting that "every genre has its methods and means of seeing and conceptualizing reality, which are accessible to it alone" (Medvedev and Bakhtin, 1978: 133). Genres, then, by means of their chronotopic orientations, become mechanisms for perceiving, conceiving, communicating about, and interpreting particular aspects of the world. They establish temporal and spatial horizons and naturalize ways of perceiving and communicating about them.

Most significantly, perhaps, Bakhtin's notion of chronotope is part of a larger epistemological framework that revolves around what he and his colleagues

identify as the "two-fold orientation in reality" that determines genres: one constituted by the chronotopic configuration of the discourse, the second by its situational context of production and reception (Medvedev and Bakhtin, 1978: 130–131). The interaction between the two orientations, then, offers an illuminating vantage point on the epistemology of genre, in regard to the linguistic and other semiotic means by which it is communicatively managed. Understandably, the pragmatics of deixis and other forms of indexicality is a primary focus of such explorations, centering on what Michael Silverstein terms the "nomic calibration" of speech event to text (Silverstein, 1993: 52).

Genre as Functional Variety or Style

A productive nexus of convergence between linguists and anthropologists interested in the social uses of language is style, encompassing the functional varieties of language associated with kinds of speakers, situational contexts, or types of utterance. The concept of genre has assumed an increasing place in this area of inquiry.

Charles Ferguson, whose work has been especially influential in the investigation of linguistic varieties, offers a concise and useful formulation of the working assumptions implicit in the study of the principal types of linguistic variety that have organized much of sociolinguistic research: dialect, register, and genre (Furguson 1994: 18–21). With regard to dialect: "A group that operates regularly in a society as a functional element . . . will tend to develop identifying markers of language structure and language use, different from the language of other social groups." With regard to register: "A communication situation that recurs regularly in a society . . . will tend over time to develop identifying markers of language structure and language use, different from the language of other communication situations." And with regard to genre: "A message type that recurs regularly in a community . . . will tend over time to develop an identifying internal structure, differentiated from other message types in the repertoire of the community."

While Ferguson frames his definitions in terms of the processes of conventionalization, the factors underlying the development of the indexical ties between linguistic and social elements, we may also consider these varieties as speech styles, along the lines suggested by Dell Hymes (1989). In these terms, a speech style is a conventionalized constellation of systemically related, co-occurrent linguistic features that contrasts with other such constellations in its indexical reference to speakers, situations, or utterance types. Characterization of a genre style, then, requires specification of the salient features that operate as diagnostic markers of that genre. Ritual wailing (*zõ*) among the Shokleng Indians of Brazil, for example, displays the following features:

1. Semantico-referential: the subject matter of ritual wailing is the death of kinsmen and affines and the affective state of the speaker as a result of that death;
2. Phonological: on the sound level, ritual wailing is marked by a sing-song intonation pattern, creaky voice quality throughout, and 'broken' voice, that is, rapid-fire glottal stops coupled with intonational modulation used intermittently on certain protracted vowels;
3. Syntactic: the syntax of ritual wailing is notably complex, with rearrangement of constituent clauses.

Taken together, these features characterize Shokleng ritual wailing as a speech style (Urban, 1985).

There are several important points to be made about genre as speech style. First, it is necessary to keep in mind that the distinctions among dialect, register, and genre are essentially analytical distinctions among dimensions of speech indexicality, and there is considerable potential overlap among the three. While it is certainly useful to recognize the various discourse types in a community's repertoire and their constituent features, and, more importantly, perhaps, to be aware that the differences are salient for members as well as analysts, it remains the case that genres may be associated in varying degrees – even quite closely – with particular kinds of speakers and situational contexts of use.

Consider the cries of Mexican market vendors, for example (Bauman, 2004: 58–81). While the calls and spiels by which vendors cry their wares may be considered and described as genres, we might equally well identify them as dialect forms, insofar as they are linked to the social category of vendors, and as registers, insofar as they are closely associated with recurrent situational contexts, namely, market days.

Local labels and category systems for ways of speaking may be keyed to any – or several – of the indexical ties between language and context. In the Chamula taxonomy of people's speech, considered earlier, for example, we may note that the contrast between 'children's improvised songs' and 'court speech,' the former combining aspects of social dialect and genre, the latter foregrounding register.

It is also worth emphasizing that notwithstanding the conventional associations that may obtain between genres, users, or situations of use, these ties are not definitive, as it is of the nature of genres that they may be used and recognized outside their customary or originary contexts. The Cuban market cry,

or *pregon*, for example, has become a resource for popular song, the best known of which is the widely recorded and disseminated 'El Amanecero,' wholly detached from the market vendors and market days with which the genre is associated. In a related fashion, selected features of a genre style may be incorporated into discourse regimented by other genre styles to impart a touch or coloration of the genre from which they are abstracted. Academics, for example, are generally familiar with lectures that smack just a bit – or more than a bit – of sermons.

The relationship between register and genre also figures centrally in conceptions of genre in the systemic functional linguistics (SFL) of M. A. K. Halliday, Ruqaiya Hasan, and their colleagues, with a strongly applied bent. Halliday defines register as "a configuration of meanings that are typically associated with a particular situational configuration of field," i.e., the focus or topic of the communicative activity, tenor, i.e., participants and their relationships, and mode, i.e., the role of language in the situation (Halliday and Hasan, 1989: 38–39). Register includes as well the linguistic features that give expression to those meanings, and, reflexively, to the register itself. Genre, then, is the schematic structure, the sequence of purposive, goal-oriented stages through which the register values are mobilized in use, in the production of particular orders of text (Halliday and Hasan, 1989: 53–68). As in other approaches to genre we have considered, descriptions of genre in SFL specify the obligatory and optional elements of the structure, their sequence, their recursive iterability, and so on. And again, SFL distinguishes between structure, the global, sequential structure of the generically regimented text, and texture, the organization of linguistic devices that endow a text with cohesion.

There is an element of ambiguity in the SFL conception of genre deriving from an ambiguity in the conception of text. Halliday views a text as "an object in its own right," a bounded, coherent, cohesive package of meanings, and as "an interactive event, a social exchange of meanings" (Halliday and Hasan, 1989: 11). Thus, some of the texts that figure in SFL analyses of genre are conventional, bounded, unitary (monologic) stretches of discourse: nursery tales, recipes, letters, academic reports, etc. Here, the analysis focuses on schematic structure and texture of particular generic forms and their textual realizations and especially the ways in which they realize the structural potential of the genre. But other analyses consider social-interactional routines of various kinds, such as service encounters or telephoning for appointments, and the resultant analytical descriptions amount to the act sequence or scenario of the speech event.

Also geared closely to pedagogical application, the conception of genre that figures in that line of applied linguistics known as English for Special Purposes (ESP) is grounded in situational contexts of language use. But whereas the relationship of genre to speech events in SFL is mediated through register, in ESP genre is **defined** not as a functional variety but as a class of events. According to John Swales (1990: 58), "a genre comprises a class of communicative events, the members of which share some set of communicative purposes." Genre, in these terms, is goal oriented, directed toward the fulfillment of some rhetorical, functional end, which in turn has a shaping influence on the schematic structure of the discourse "and constrains the choice of content and style"; genre, that is, is organized in terms of form–function interrelationships.

The study of genre in ESP tends to focus on language in academic and professional settings and to foreground two principal dimensions of generic form: schematic structures, described in terms of 'moves,' and surface level stylistic features, especially syntactic features such as sentence length, nominalization, prepositional phrases, and the like. Notwithstanding the definition of genres as classes of communicative events, the framing of structural elements as 'moves' is the closest that ESP analysis comes to event-ness, insofar as it suggests a series of purposive acts that make up the scenario of an event. In practice, the substantive focus of genre-oriented analysis in ESP turns out to be on textual forms of various kinds, usually written, in academic and professional settings, such as research articles, dissertations, sales promotion letters, job application, and legislative documents.

Genre as Solution to Recurrent Communicative Problems

Most of the conceptions of genre treated thus far conceive of genre as a nexus of the linguistic and the social, but with primacy accorded to the former. Contrastive in this regard is the approach to genre proposed by Thomas Luckmann (1995) and his colleagues (Günthner and Knoblauch, 1995) from the vantage point of social-constructivist sociology and the sociology of knowledge. Luckmann defines communicative genres as socially constructed communicative models for the solution of recurrent communicative problems. In Luckmann's view, some of the communicative work of social actors consists of spontaneous communicative acts, in which the speaker manages a communicative task in an ad hoc, contingent manner. In other situations, however, a social actor draws from his or her stock of socially acquired knowledge a ready-made, conventional

model that seems to fit the communicative task at hand, consistent with the speaker's intentions. Such conventionalized solutions have coalesced out of repeated engagement with recurrent communicative problems to the point where they have become routinized and more or less obligatory and have entered the social stock of knowledge, though, like all knowledge, they will be differentially distributed within society. The communicative problems for which genres provide routinized solutions "tend to be those which touch upon the communicative aspects of those kinds of social interaction which are important for the maintenance of a given social order" (Luckmann, 1995: 228). Within the broad scope of those aspects of social life that are communicatively constituted, in Luckmann's view, genres occupy the "hard core," the regularized and routinized sector of communication in social life.

What is important to the social order will be historically and cross-culturally variable, and so, then, will repertoires of communicative genres, although we may anticipate certain universals or broad tendencies, founded in the universality of the human condition. As social regimes for the solution of recurrent communicative problems, genres will integrate social and communicative elements. In Luckmann's conception, genre represents a comprehensive framework for the integration of:

1. situational factors, i.e., types of recurrent communicative situations: is the genre obligatory, optional, frequent, acceptable, proscribed in a given type of situation?
2. social factors, i.e., aspects of the social organization of participation and protocols for the management of interaction;
3. communicative means, i.e., linguistic, paralinguistic, prosodic, kinesic, formulaic, etc.
4. topical or thematic elements.

For the description and analysis of these constituent elements, Luckmann refers to – and relies upon – analytical methods and approaches drawn from the adjacent disciplines concerned with the relevant aspects of communication in context, such as linguistics, linguistic anthropology, folklore, the sociology of communication, and so on.

Within the broad domain opened by their conception of genre, Luckmann and his colleagues identify several problems of special interest. Luckmann's own work has focused on reconstructive genres, such as gossip and narrative, that serve as communicative means for reconstruction and reflexive engagement with events and social interactions; events are transitory, and reconstructive genres endow them with tangible, replicable substance and coherence. Also of interest is genre as a framework for the regimentation of perspective-setting and perspective-taking in the reciprocal calibration of perspectives: the routinized nature of genre and its place within the social stock of knowledge serves to align participants to each other and to the social agendas with which they are engaged.

Dialogic Approaches to Genre

One of the most influential of current approaches to genre in social life is that of the Russian theorist of language and literature, Mikhail Bakhtin. Bakhtin's conceptions of genre have proven especially stimulating and productive among linguistic anthropologists, who have built upon and elaborated various aspects of his theoretical framework.

Bakhtin's interest in genre derives from his core notion of utterance, the basic unit of language in use. Language, in Bakhtin's view, is realized in concrete utterances, the intersubjective, joint accomplishment of a speaker (or author) and an interlocutor. One of Bakhtin's concerns, then, is to identify what constitutes an utterance as a unit: bounded, coherent, whole. The concept of genre, in Bakhtin's framework, provides a critical perspective on this problem. "Each utterance," Bakhtin writes, "is individual, of course, but each sphere in which language is used develops its own *relatively stable types* of these utterances. These we may call *speech genres*" (Bakhtin, 1986: 60).

We may note in this definition that genres are grounded in spheres of activity: the generic regimentation of discourse, in Bakhtin's schema, represents a constitutive feature of domains of social practice. Spheres of activity likewise define semantic or thematic fields, which inform the content of the speech genres that organize those domains. In addition to spheres of activity, genre is inextricably bound up with functional style. "Functional styles," in Bakhtin's view, "are nothing other than generic styles for certain spheres of human activity and communication" (Bakhtin, 1986: 64), that is, they are generically organized – indeed, generically constituted. Style is one aspect of the formal organization of genre; compositional structure is the other: "all our utterances have definite and relatively stable typical *forms of construction of the whole*" (Bakhtin, 1986: 78). And finally, genre is an organizing framework for participation in communicative interaction. A key notion here is *addressivity*, a fundamental aspect of utterance. Every utterance, in Bakhtin's conception, is addressed to someone, in anticipation of a response. It follows, then, that "each speech genre in each area of speech communication has its own typical conception of the addressee, and this defines

it as a genre" (Bakhtin, 1986: 95). In sum, genre, for Bakhtin, is the nexus of domains of activity, content, style, compositional structure, and structures of communicative participation.

What is it that renders a generically organized utterance a bounded whole? First, says Bakhtin, is "a *change of speaking subjects*, that is, a change of speakers." Genres, then, regiment speech exchange – turn taking and access to the floor – at the same time as they frame the utterance. Second, genre incorporates various modes for the finalization of the utterance, opening the "possibility of responding to it." Finalization is determined by three factors:

1. semantic exhaustiveness of the theme, a matter of coherence;
2. the speaker's plan, or speech will, manifested primarily in the choice of a particular speech genre;
3. the mechanisms of closure inherent in genre-specific compositional structures.

The essential importance of the finalization of the utterance lies in its effect of opening the possibility of responding to it; the formal finalization effected by generic boundedness is a metapragmatic invitation to response, a key basis of the dialogic principle (Bakhtin, 1986: 71–77).

If genre provides a framework to account for the boundedness of utterances, it provides as well for the transcendence of those boundaries, that is, in Bakhtinian terms, for the dialogic qualities of the utterance. Dialogue is the central principle of Bakhtin's conception of language, the relational dynamic by means of which society is communicatively constituted and language is socially constituted. Bakhtin's abiding concern was with the ways in which all discourse resonates with "the words of others," that is, with the ways that any utterance presupposes and responds to prior utterances and anticipates future ones. For Bakhtin, this dialogic process is both a matter of communicative practice (the intersubjective work of producing dialogic relationships) and of the concomitant links that are thus established between and among utterances as they circulate through society and through time. In Bakhtin's conception, dialogue extends far beyond a simple dyadic exchange: rather, "each utterance is filled with echoes and reverberations of other utterances to which it is related by the communality of the sphere of speech communication" (Bakhtin, 1986: 91). With regard to genre, dialogic relationships are manifested especially in the reciprocal generic organization of utterance and response, in the alignment of an utterance in its production to the generic type, which has shaped prior utterances of the same type, and in the assimilation of genres to other genres, especially in what Bakhtin terms secondary genres, which "absorb and digest various primary (simple) genres" (Bakhtin, 1986: 61–62).

Linguistic anthropologists have developed upon Bakhtin's dialogic approach to genre as a vantage point on speech indexicality. To Bakhtin's recognition of the importance of addressivity and of genre as a mechanism for the regimentation of participation in communicative interaction, these scholars bring a more systematic perspective on the social organization of participation, adapted principally from Erving Goffman's (1981) approach to participant roles and structures; to his fertile insight into genre as an orienting framework for the dialogical alignment of utterances, they bring a more systematic perspective on textuality, entextualization, and contextualization; and to his essentially literary frame of reference, they bring an ethnographic empiricism that seeks to elucidate the dynamics of dialogicality in specific social, cultural, and historical contexts (see 'Genre in Context' below).

Central Problems in the Study of Speech Genres

What Counts?

The various conceptions of genre reviewed in the preceding sections raise a number of fundamental questions concerning the nature of genre, perhaps the most fundamental of which is what order (or orders) of linguistic phenomena genre comprehends. What counts for the purposes of generic description, classification, or analysis?

For most classic conceptions of genre, the answer is simple and apparent: texts. A genre is a typological category for the classification of texts, themselves conceived essentially as verbal objects. Indeed, because much generic classification has been in the service of archiving, indexing, or the organization of published text collections, the objects of such classification have been text-artifacts, the physical inscriptions of verbal texts (Silverstein, 1993: 38). Not all classificatory or typological approaches to genre center on texts, however. A communication-centered approach, for example, may conceive of genre as a class of message types (Ferguson, 1994); a functional one may center on genre as a class of end-oriented communicative events (Swales, 1990). In Bakhtin's dialogic framework, a speech genre is a type of utterance, a bounded stretch of spoken discourse that coincides with a turn-at-talk. At the same time, however, utterance is an interactional unit, or an intersubjective one, insofar as it is addressed to an

interlocutor and anticipates a response. In assessing conceptions of genre, then, it is important to attend to the objects of generic systems.

Another consideration having to do with what kinds of things are comprehended by genre is what counts as a token of the generic type. In most conceptions of genre, there is an assumption, tacit or explicit, of wholeness or completeness: types are conceived in terms of their full realization. In formal characterizations of genres, where the genre is described or defined in terms of its constituent elements, analysts may make a distinction between obligatory elements, which make up the irreducible minimal form of the genre, and optional elements, which may be present but need not be for the text to count as legitimate. Propp's formal definition of the Russian magic tale is a classic case in point; Halliday and Hasan's distinction between the obligatory and optional elements of a generic structure potential is another.

Given the normative, typological set toward wholeness in conceptions of genre, it is perhaps not surprising – though on reflection it is striking – that there is almost no considered treatment of incompleteness, of a lack of generic closure. In a noteworthy exception, Hanks, using Bakhtin's notion of finalization, distinguishes between lack of finalization that rests on the absence of necessary formal constitutents, and lack of finalization which recognizes that any utterance is open to revision and reformulation. He notes that the former may be finalized by interpretive uptake, notwithstanding the formal "blank spots," while the latter remains the condition of any utterance (Hanks, 1996a: 243–246). Hanks' observations raise the related question of whether wholeness is considered to be a matter of production only, or involves the relationship between production and reception. Formal perspectives on wholeness tend toward the former; interactional and interpretive ones open out toward the latter.

A further dimension of the problem of wholeness or completion that is highlighted by interactional approaches has to do with monologic perspectives on production versus perspectives that allow for – or even take as a generalizable given – participant co-production. Most approaches to genre, as to text, are implicitly monologic: generically organized texts (or utterances, or messages) have one 'author.' Again, social interactional and dialogic approaches open the way to consideration of various dimensions of co-production, whether it is a matter of multiple participants jointly and interactionally producing the full text (consider knock-knock jokes as a simple case in point), of what students of language in interaction call recipient design, or of the interrelated and intersubjective dynamics of production and interpretation.

Strongly contrastive with typological, classificatory conceptions of genre that serve to categorize verbal forms of one sort or another – texts, utterances, events, etc. – are more practice-oriented perspectives that conceive of genre as a guiding framework for communicative practice. Luckmann's notion of genre as a solution to a recurrent communicative problem is one such approach. In Hanks's conception of genre as a relatively stable prefabricated aspect of practice to which participants have access as they enter into and sustain engagement in communicative interaction (Hanks, 1996a: 233), or Briggs and Bauman's (1992) conception of genre as an orienting framework for the production, reception, and circulation of texts, genre consists of cognitive schemata. Texts and utterances remain important, not as the primary objects comprehended by genre, but as the products of communicative practice aligned to genre.

Closely related to the question of what kinds of phenomena are subsumed by generic categories is an additional 'what counts?' question, namely, what part of the linguistic domain within a society or speech community is encompassed by genre? What is the reach of genre within the overall linguistic economy?

The most broadly inclusive view is that all discourse is generically organized – there is no verbal practice that escapes generic regimentation. Bakhtin is a proponent of this view. In his conception of genre, it is essentially axiomatic that all linguistic production is generically organized, a corollary of the principle that all communication is dialogically – that is, socially – constituted. This principle is certainly difficult to demonstrate empirically, and those descriptive accounts that seem to be all encompassing, such as Gossen's taxonomy of Chamula genres, actually include a large, amorphous super-category that is generically undifferentiated, such as ordinary speech.

More empirically and practically useful is the position that genre encompasses the routinized or schematized forms of communicative practice, those that have been crystallized in social usage and that have become part of the pool of social knowledge, intersubjectively recognized by participants. Genre, in this conception, contrasts with spontaneous or emergent communication, organized on the spot to answer communicative contingencies for which there are no ready-made and readily accessible models (Hanks, 1996a: 233; Luckmann, 1995). Certainly, empirical investigations of genre have tended to focus on the relatively clear-cut and strongly routinized regimes of speech production, content to relegate

the spontaneous and emergent forms to some residual category such as 'everyday language' or 'ordinary speech.' More difficult to recognize and grasp are those utterances that fall between the poles, such as genres still in the process of coalescing into routinized regimes, or utterances marked by formal features that characterize this or that routinized genre, sufficient to endow them with the coloration of genre, but not to establish them as fully realized tokens of the generic type (Hymes, 1989).

Relevant to these considerations as well is the relationship between the scope of the generic field and the metapragmatic awareness of participants. The problem has at least two dimensions, one having to do with the sociology of knowledge, the second with cultural focus. The simple mapping of a system of genres onto a culture or a society or a speech community rests on an assumption of cultural homogeneity and a general pool of cultural knowledge held by all. Such assumptions are clearly untenable by the best standards of the sociology of knowledge, which demands that we investigate empirically and specify closely what the sociology of genre might be in any social formation. Note, for example, that Gossen's breakthrough description of Chamula genres of verbal behavior is actually an account of that portion of the genre system on which at least six of seven male informants agreed. Gossen found other named forms of verbal behavior among the Chamula, but without agreement about where they fit in the overall system or information on how Chamula women discriminate among orders of people's speech. Note also that the preponderance of accounts in the ethnographic literature on genre report the knowledge of experts, cultural specialists with a more detailed and nuanced view of ways of speaking than most lay people command. Studies of genres that are key communicative resources within specific institutions, such as education or law or curing, have the virtue of specifying what the social base of these resources may be. It is also important to bear in mind the distinction between recognition of a genre and the competence to use it. To be sure, generic competence must include as well the knowledge and ability to be an audience member, to receive and interpret a generically organized utterance. Thus the question of the scope and reach of genre must take account of social distribution, degrees of expertise, recognition versus productive competence, the sociology of participation, and other like considerations.

Just as there are differences within social groups with regard to the scope and reach of genre, there are differences across cultures in the scope and articulation of the generic field. Ethnographers of speaking are understandably drawn to places where speaking is a cultural focus, where there is a relatively high degree of metapragmatic awareness of and reflexive engagement with ways of speaking. In such milieux, the generic field is more extended, more complex in its organization, more nuanced in its generic discriminations. One has only to compare the exuberant attention to ways of speaking in Afro-Caribbean societies, for example, to the laconic disinclination toward talk about talk in the Canadian Maritimes (Abrahams and Bauman, 1971; Bauman, 2004: 109–127).

Genre in Context

Virtually all of the conceptions of the metapragmatic scope of genre considered in the preceding section go beyond the definition of what counts as genre and the delineation of the domains of communicative practice that are organized in generic terms to the examination of genre in terms of wider fields of interrelationship. In broadest scope, genre may be conceived as an indexical field, implicating a range of associational relationships. The inventory of contextual factors and relations treated in the literature is broad; different theories foreground different aspects of context and dimensions of interrelationship.

Perhaps the most general contextualist perspective uses genre as a vantage point on culture and history more generally, as a key to the elucidation of larger cultural systems. This approach is consistent with – indeed, continuous with – the philological foundations of Americanist linguistic anthropology. Gossen's Chamula study is a case in point, and there are many others. As one would expect, the approach is most productive in the ethnographic description of societies in which ways of speaking represent a cultural focus, heavily ideologized, a criterion for individual and social differentiation, a resource for virtuosic display in performance, the focus of reflexive evaluation, and so on. Work of this kind generally treats the field of genre systemically as well, articulating genres in relation to each other within the overall communicative economy, that is to say, genres in the context of other genres.

A second broad perspective on context considers genre in terms of domains of use, conceived as spheres of activity, fields, institutions, or situational contexts. These constructs are all well-established sociological, anthropological, or phenomenological frames of reference for taking account of the nexus of purposeful activity, social organization, and cultural formations. In their various ways, they offer conceptual vantage points on the engagement and mutual alignment of participants, meaningful contexts for action, and orienting frameworks for the production and

interpretation of discourse. That is to say, they are part of social theory more generally, adapted to considerations of genre, but not as a rule a primary focus of genre theory itself.

Those conceptions of genre that tie it to register, itself defined in terms of recurrent situational contexts, assign the most explicit weight to this dimension of context, but situational contexts of use are fundamental to a much broader range of genre-centered considerations. One especially productive line of investigation examines the varying ways in which and degrees to which particular genres in a speech community may be formatively adapted to their immediate contexts of use. In the most comprehensive study of this kind, Briggs (1988) examines a range of speech genres in Northern New Mexico and elucidates a continuum from the close situational grounding of historical discourse and proverbs to the markedly loose coupling of prayers and religious songs to the immediate, specific contexts in which they are performed. Analysis of this kind requires close attention to the formal means and device by which discourse may be anchored to its context of use, such as deictics, phatic gestures to interlocutors, reflexive references to the act of communication itself, or any other. Such contextualization cues will vary across genres. Likewise, it requires close attention to forces that work in the opposing direction, that is, to how different kinds of generic regimentation may render an utterance or a text relatively impervious to and detachable from the situation in which it is used, such that form or meaning remains relatively constant from one context to another. It is illuminating in this regard to track the use of what is considered to be the same genre across different kinds of situational context, recalling, as we must, that notwithstanding conceptions that define genres in terms of specific situational contexts, it is in the very nature of genre to be recognizable outside those conventional settings. Empirical investigation reveals clearly that certain genres in any given community's repertoire may be adapted to multiple contexts. Myths that are primarily performed in shamanic rituals among the Warao of Venezuela may also be rendered in other modes, such as pedagogy or competitive exchange (Briggs, 1993). Such rekeyings of genre often elude description, obscured by the tendency to concentrate attention on the primary, default context or frame with which a specific genre is conventionally associated. For any given iteration, the intertextual field reaches back to antecedent utterances at the same time that it anticipates prospective ones. This is true, to be sure, within speech events as well as across them. Within a single event, we might think of the antecedent (that is, presupposed) and anticipated (that is, entailed) discursive context of any utterance as making up its **co-text**: in the case of a lecture, for example, the introduction of the speaker by a host sponsor or the question and answer period that follows the talk.

In the case of the Warao myths, however, our purview has extended beyond the individual situational context. While the empirical point of departure is the situational context or speech event, recontextualizations of the kind we have been considering establish relationships of intertextuality that transcend the individual situation, fields of textual interrelationship consisting of the various instantiations of a generic model. These generic relationships, however, represent but one order of intertextuality that extends the reach of discourse beyond the bounded speech event. Irvine's (1996) pioneering analysis of the dialogues implicated in the performance of *xaxaar*, a Wolof genre of insult songs sung to new brides, elucidates an intertextual field that begins with discussions between patrons and the griot singer who is to compose and perform the song, continues with the core performance at the ceremony in which the new bride moves to the groom's family household, and reaches ahead to a range of contexts in which the song is reperformed, discussed, evaluated, and so on.

One corollary of this field of intertextual relationships is that *xaxaar*, as a genre, also implicates a complex set of participant roles and structures: patrons and griot in the preliminary discussions, griot, bride, and other audience members in the wedding ceremony, various members of the community who talk about the performance and its meanings in the aftermath. Here the convergent perspectives of Erving Goffman (1981) on the interaction order and dialogic approaches to genre come together in the recognition that genres implicate sets of participant roles and participant structures, presupposed frameworks of mutual alignment, both within and between situational contexts of use. Bauman (2004: 128–158), for example, has analyzed a series of genres for which the process of actualization involves a mediational relay, setting up a complex set of participant roles and structures requiring the decomposition of classic dyadic speaker-hearer or performer-audience models.

Institutional contexts come to the fore most commonly in functionally oriented explorations. There is a growing literature, for example, on the role of laments in the assuagement of grief, tying poetic form to ritual function, and a sizable body of work on political oratory and social control, likewise linking form to function. In explorations of genre in SFA and ESP, both of which have a strong orientation toward practical application, certain institutional contexts, especially education, loom especially large;

pedagogical and expository genres such as the school essay and the research proposal are viewed as at least partly constitutive of the educational institutions in which they figure.

Normative Types Versus Emergent Forms

Typological approaches to genre are characteristically framed in terms of static categories, normative, bounded, and complete. In an effort to provide a critical corrective to these static typological approaches, genre theorists – especially those oriented toward practice – have turned increasingly to conceptions of genre that view genre as flexible, contingent, and emergent, a discursive accomplishment rather than the realization of a norm. These contrastive dynamics may be framed in a variety of ways; many are alternative or complementary perspectives on contextualization, discussed in the preceding section.

One salient dimension of fixity versus flexibility has to do with the relative tightness or looseness of the associational linkage between a given genre and a corresponding order of situation. For some genres, the association is so close that the event cannot be considered fully realized, authentic, or legitimate in the absence of its authorizing genre. Indeed, the tie may be so fundamental that the genre and the event may be labeled by the same term: the lecture, once again, is a case in point. It is close associations like this that enable definitions of genres as types of events. At the opposite end of the scale, certain genres may be so strongly proscribed within or incompatible with the conventional expectations of particular kinds of events that the likelihood of their occurrence approaches the vanishing point: a dirty joke during a Baptist religious service, for example. In between these two poles there will be in any speech community a sliding scale of expectation and appropriateness with regard to the occurrence of a given genre in a given situational context. It is essential to bear in mind, however, that genres remain recognizable outside their conventional contexts, and to be open to surprising and creative uses of genres – or failure to use them – where such usage is unexpected or even proscribed, demands special accounting, may even have the capacity to transform the context itself. The early Quakers' refusal to swear judicial oaths, for example, was deeply shocking to all observers and brought down severe penalties on those who refused to swear, but led ultimately to the acceptance of affirmation as the functional equivalent of oaths in British and American judicial proceedings.

Much the same kind of associational variability may obtain between a given genre and a particular kind of social role or relationship. Consider the roles of sports announcer, or toastmaster, or carnival barker, all defined in terms of the production of particular genres, or so-called joking relationships, which are instantiated through the use of licensed insults of a kind not sanctioned between people who do not stand in that relationship. Other roles may be associated with certain genres, which are nevertheless not constitutive of that role: after-dinner speakers often tell jokes, but need not.

Another consideration keyed to situational contexts of use is whether the use of a given genre is scheduled or spontaneous. Scheduling, that is, performance at a specified time and place, is especially conducive to coordinated participation, for performers, audience members and other participants. Scheduled events are often cultural performances, occasions on which a community's values and symbols are placed on display before an audience: festivals, feasts, fairs, rituals, spectacles, theatrical enactments, and the like. Such events tend also to be programmed, with a relatively set sequence of constituent acts: the collect comes before the mass, the introduction of the speaker precedes the lecture, the acceptance speech follows the nominating speech, and so on. In certain cases, the use of a given genre may be programmed without being scheduled; a greeting occurs at the beginning of an encounter, a leavetaking ends it. Other genres may be spontaneous. These tend not to be the obligatory ones: telling a joke, for example, during the course of a sociable encounter.

If we shift our focus from situational to discursive context, other significant dimensions of fixity versus flexibility come to the fore. In particular, in dialogic conceptions of genre as an orienting framework for the production and reception of particular kinds of texts which will be bound together in a relationship of intertextuality, the calibration of that intertextual relationship offers us a vantage point on the dynamics of normativity and emergence in discursive practice. The correspondence between a particular utterance and the generic schema – or other exemplars of the generic class – is never perfect. Contingent elements of contextualization inevitably come into play, creating links to the co-text, the ongoing social interaction, functional agendas, and other contextual factors that interact with generic orienting frameworks in shaping the production and reception of the utterance. These in turn will affect the ways in which the constituent features of the generic framework are deployed, opening the way to generic reconfiguration. Thus, generic intertextuality necessarily involves the production of an intertextual gap (Briggs and Bauman, 1992). The calibration of the gap – its relative constriction or amplification – has significant correlates and effects. Certain acts of communication

may achieve generic orthodoxy by hewing closely to generic precedent and aligning the utterance to conventional practices for achieving routine ends under ordinary circumstances. Think of the boilerplate templates for the generation of legal documents – wills, contracts, leases, and the like. By contrast, stretching the intertextual gap allows for the adaptation of generic frameworks to emergent circumstances and agendas, such as the parodies of political speeches that flower during election campaigns. Such adaptive transformation may involve manipulation of any of the formal, functional, and thematic elements by which an utterance may be tied to generic precedents or to the assimilation of an utterance to more than one genre, blending the formal and functional capacities of each of the genres thus invoked. Such generic mixing may yield what Bakhtin designates as "secondary genres," which "absorb and digest various primary (simple) genres" (Bakhtin, 1986: 62), assimilating them to more encompassing generic structures. Oratory is a good case in point, as characteristically incorporating stories, aphorisms, proverbs, or other genres. Or, they may yield various hybrid forms out of the merger of two primary genres, such as the cante-fable or the riddle tale, which are themselves conventional genres. Also possible is a more *ad hoc* generic blending, produced in response to emergent circumstances, such as the mythically structured narrative of personal experience told by Pete McGuff to the young Edward Sapir in the course of an ethnographic encounter (Silverstein, 1996).

The calibration of intertextual gaps offers a useful vantage point on the ideology and politics of genre. Within any speech community or historical period, genres will vary with regard to the relative tightness or looseness of generic regimentation, but certain genres may become the objects of special ideological focus. Prescriptive insistence on strict generic regimentation works conservatively in the service of established authority and order, while the impulse toward the widening of intertextual gaps and generic innovation is more conducive to the exercise of creativity, resistance to hegemonic order, and openness to change. These factors will be closely tied as well to hierarchies of value and taste (which genres are evaluated as relatively higher, better, more beautiful, more moral) and to the social regimentation of access to particular generic forms (who can learn them, master them, own them, perform them, and to what effect).

There is a temporal, sequential dynamic implicit in these processual perspectives on emergence, intertextuality, hybridization, and the like, that represents a significant departure from the static, atemporal perspective of classic typological approaches. Temporality becomes more explicit and broader in scale in a developing line of inquiry that focuses on the social history of genres (e.g., Hanks, 1987; Kuipers, 1998). There are three principal – and allied – rubrics under which the history of genres as social practice has been concentrated: the advent of modernity, the spread of literacy, and the experience of colonialism. At its most productive, this work combines precision of generic description in each phase of historic transformation, awareness of form-function-meaning interrelationships, and rigorous historiography.

The ability to speak using the structured rule-governed system of language is a uniquely human characteristic. With an ease and simplicity that is regularly taken for granted, spoken communication imparts information regarding a speaker's message by orchestrating the language domains of semantics, syntax, morphology, phonology, and pragmatics. Typically one thinks of the spoken message as being contained solely within this linguistic code. However, there is also a great deal of information conveyed through associated paralinguistic content as well as through the motor processes of the speech act itself. The speech signal is essentially a highly interlinked and well-organized conglomeration of acoustic energy that can be represented by time, frequency, and intensity information. These domains allow for quantitative physical measurement of the signal as well as qualitative perceptual judgments by listeners. Such qualitative and quantitative assessments of speech each provide a wealth of information about an individual, ranging from his or her sex, age, and cultural and socioeconomic background, to physical health and emotional state.

The process of speech production itself, that is, the generation of the appropriate sounds necessary to convey a speaker's message, is inordinately complex. Simply put, this intricate process involves the coordination of over 100 individual muscles, numerous cranial and spinal nerves, cortical and subcortical neural areas, and the cognitive processes necessary to generate meaningful sound combinations from the raw

physiological materials. That is, when respiration, phonation, articulation, resonance, and prosody are combined in a well-executed manner, the end product is a clear and meaningful speech code that contains a message. However, a breakdown anywhere in these interdependent physiological systems, spanning from the diaphragm to the cortex and to the outermost border of the lips, can lead to measurable changes in the speech acoustic output. The neurological and physiological substrates necessary for speech production may be altered by a wide variety of neurological or psychiatric disease processes, often altering the final acoustical properties of speech in a somewhat predictable manner. Hence, measurable information in the acoustic output of individual patients may provide valuable clues for diagnosing certain diseases, following the course of disease progression, assessing response to medical treatment, or a combination of these.

Certain voice features may change in healthy people as a result of their emotional state (e.g., anger), fatigue, or pharmacological intervention (e.g., in response to the sedative effects of alcohol). In addition, changes in speech and voice patterns may reflect certain pathological changes resulting from disease processes. For example, in 1817, James Parkinson described individuals suffering from the disease that today bears his name as showing changes in their speech that made them "become scarcely intelligible" (Parkinson, 1817).

Although the voice and speech production changes associated with various diseases are readily detected on a perceptual level, studying them in an objective and quantitative manner can be a logistically difficult task. Systematic attempts to classify and measure voice characteristics date back to the 1960s. Not surprisingly, these analyses were often compromised by the limitations of the technology of the time. With the advent of modern computing platforms and applications, and with affordable access to high-fidelity digital recording techniques, the analysis of voice acoustical properties has become more accurate, reliable, practical, and relatively inexpensive.

Recording and Data Processing Equipment

It is now possible to record research-quality acoustic information directly to a computer hard drive using a high-quality microphone, an external analog-to-digital converter (e.g., a sound card), and a simple digital connection. The acoustic signal is captured by the microphone (preferably a condenser microphone with response characteristics in the 20–20,000-Hz frequency range), converted to digital code by the sound card (i.e., preferably an external device that does not rely on the computer for power, processing, or clock information), and transmitted to the computer via simple digital connection (e.g., Firewire/USB). In this way the data can be stored in digital format and analyzed for their acoustic content without a loss of information. Recording quality is affected by the equipment and should be sufficiently high to capture and accurately represent the acoustic properties of the human voice. A sampling rate of at least 22 kHz with 16-bit intensity quantization is both appropriate and widely available.

Because a great number of different measurements can be made from a short sample of speech, the software package used for analysis is dependent on the needs of the researcher and his or her particular area of interest. There are many commercially available (e.g., Kay Elemetrics Computerized Speech Laboratory, Kay Elemetrics Corp., 2004) as well as free 'shareware' programs available (*PRAAT*; Boersma and Weenik, 2004) for computerized speech analyses. These programs generally provide a package of recording, manipulation, and analysis tools with easy-to-use graphic user interfaces, designed to extract frequency, intensity, and time measures from acoustic samples.

Neurobiology of Speech Production in Common Neurodegenerative Disorders

The production of speech is a voluntary process that relies heavily on motor areas in the prefrontal cortex, the primary motor cortex, premotor cortex, associative motor areas, and Broca's area. Important connections that lead to the transfer of cortical motor commands to the lower motor neurons include the corticobulbar and corticospinal tracts, collectively known as the internal capsule. Typically, localized damage to these upper motor neurons results in spastic dysarthria, whereas damage to the lower motor neurons results in a flaccid dysarthria (Duffy, 1995).

Of the many subcortical structures, the one crucially involved in any voluntary motor activity, including speech production, is the basal ganglia and its functional circuitry. The basal ganglia include several nuclei: the caudate, putamen, two parts of globus pallidus (internal and external) and two compartments of substantia nigra (pars reticulata and pars compacta), subthalamic nucleus, ventral tegmental area, and nucleus accumbens. Of these, the caudate and putamen are, together, referred to as the striatum. The striatum receives its major afferents from cortex (excitatory glutamatergic projections) and substantia nigra pars compacta (dopaminergic projections). The major output structure of the basal ganglia is

the thalamus (especially the ventrolateral portion), which in turn provides feedback and modulates cortical activity. The basal ganglia exert influence on the thalamus via two pathways; a direct pathway, which sends inhibitory signals, and an indirect pathway, to which it sends excitatory signals (Murdoch, 2001). Although the exact role of separate components of the basal ganglia on speech is poorly understood, the system is known to be responsible for maintaining postural stability and static muscle contraction – providing a framework for voluntary skilled movements and the regulation of amplitude, velocity, and the initiation of movements, as well as sequencing of movements (Duffy, 1995). Damage to the basal ganglia can often result in either hypokinetic or hyperkinetic dysarthria.

Another structure that also plays a role in speech production, especially the fluency of speech production, is the cerebellum. The cerebellum has connections with both primary and premotor cortex via the ventral thalamic nuclei, and it also gains access to the corticobulbar and corticospinal tracts (Duffy, 1995). It is able to coordinate and modify both planned and ongoing speech movements. Damage to cerebellum produces an ataxic dysarthria.

Voice and speech production reflect complex motor activity, thinking processes, and emotional processes. Therefore, certain neurological disorders related to those processes tend to affect speech as well. As a consequence, language, speech, and voice analysis may provide a noninvasive and inexpensive window into underlying neurological pathologies.

Speech and Voice Acoustic Characteristics in Neurodegenerative Diseases

Parkinson Disease

Parkinson disease (PD) is a progressive neurodegenerative disorder that affects the motor system and cognitive functioning. The selective destruction of the nigrostriatal dopaminergic neurons leads to a disruption of the basal ganglia circuitry, thus leading to the outward symptomatic presentation associated with the disease. The underlying pathology is manifest in several classic motor symptoms: bradykinesia (motor slowness), akinesia (difficulties in movement initiation), rigidity (stiffness in muscles), and resting tremor, which occurs in the absence of voluntary motor behavior (Barbeau, 1986). The underlying neurodegeneration is also associated with affected speech musculature compromising muscles responsible for respiration, laryngeal control, and articulation. The associated speech and voice impairment in PD is collectively termed hypokinetic dysarthria. Perceptually, hypokinetic dysarthria is characterized by monopitch, monoloudness, reduced stress, imprecise consonants, and inappropriate silences. In addition, hypokinetic dysarthria is characterized by hoarse, breathy quality of voice and short rushes of speech (Darley *et al.*, 1972). The acoustic findings of Parkinsonian speech, reflecting monopitch and monoloudness, include a decrease in fundamental frequency (F_0) variability and range, with increased F_0 variability found on vowel prolongation tasks, and a decrease in maximum intensity range and laryngeal respiratory coordination deficits (e.g., voice onset time). In addition, there is a smaller distinction between different vowel productions as measured from decreased acoustic differentiation and resonant energy transitions in vowel–consonant production than in control subjects, reflecting the imprecise consonant production (Goberman and Coelho, 2002).

Interestingly, hypokinetic dysarthria is the only type of dysarthria characterized by increased speed of reading, most likely related to the phenomenon of festination. The increased reading rate is achieved by compromising articulation accuracy. However, with the progression of the disease, this compensation is not sufficient to maintain typical speech rate. As the disease process becomes more severe, articulation is less precise, and reading rates become slower. The inability to initiate movement of articulators is reflected in the increased number and duration of pauses. Prosody measures are characterized by decreased intensity variability and fundamental frequency variability, adding to the perceptual monotonous and reduced loudness of Parkinsonian speech.

Huntington Disease

Huntington disease (Huntington chorea) is a genetic neurodegenerative disease that affects the basal ganglia and parts of the cortex. The selective destruction of GABAergic neurons within the caudate nucleus, and later the substantia nigra, leads to the disruption of the basal ganglia system, and ultimately disinhibition of the thalamus (Murdoch, 2001). The cardinal symptom of the disease is chorea, a variety of uncontrollable involuntary movements, accompanied by bradykinesia of voluntary movements and dementia later in the course of the disease (Strange, 1996).

These involuntary movements interfere with speech production. Speech deficits frequently associated with Huntington disease are known collectively as hyperkinetic dysarthria. Perceptual analysis of choreic speech is predominantly characterized by intermittently harsh voice with a strain-strangled voice quality. In addition, imprecise consonants, prolonged intervals,

irregular pitch fluctuations, variable speaking rate, inappropriate silences, distorted vowels, and uncontrolled variations in loudness have also been reported (Darley *et al.*, 1972).

Acoustically, vowel prolongation tasks have revealed the presence of lower-frequency segments, vocal arrests, and reduced maximum vowel duration, as well as an increased standard deviation of fundamental frequency in patients with Huntington disease (Ramig, 1986; Zwirner *et al.*, 1991). Some studies revealed normal values for shimmer and jitter accompanied by low values of harmonic-to-noise ratio (Ramig, 1988), whereas others found jitter to be significantly higher in a Huntington diseased voice, with the other perturbation measures unchanged (Zwirner *et al.*, 1991).

A number of acoustic studies have focused on the speech motor timing deficits in this disease. The most prominent features observed in a consonant vowel production within the context of a sentence included increased variability of sentence utterance duration and voice onset time (Hertrich and Ackermann, 1994). The measurements of alternating motion rates also revealed increased syllabic durational variability as well as increased syllable duration (Ackerman *et al.*, 1995).

Progressive Supranuclear Palsy (Steele-Richardson-Olszewski Syndrome)

Progressive supranuclear palsy is a neurodegenerative disorder characterized by the presence of neurofibrillary tangles and cerebral atrophy, and with the exception of the frontal lobes, the cortex is generally unaffected. However, degeneration is observed in a number of subcortical nuclei, including parts of basal ganglia (subthalamic nucleus, substantia nigra, and globus pallidus), red nucleus, and superior colliculli, as well as in a number of brain stem nuclei (Duffy, 1995).

The symptomatic picture of the early stages of the disease is very similar to PD. Patients experience rigidity, bradykinesia, and postural instability. The distinguishing feature, usually developing later in the course of the disease, is a gaze palsy that manifests as a paralysis of vertical downward gaze. Speech disturbances are not typically the predominating complaint in most patients at the time of the diagnosis, and they may take a form of generalized dysarthria with the presence of dysphagia. However, there is no single type of dysarthria characteristic for the disease. Usually patients present with a mixed dysarthria with varying degrees of hypokinetic, spastic, and to a lesser extent, ataxic elements (Duffy, 1995). Interestingly, the presence of dysarthria becomes a useful way to distinguish between PSP and PD. Perceptually, the prominent speech characteristics related to the PSP occur more often than in PD and include monopitch hoarseness, nasal emission, excess and equal stress, hypernasality, imprecise articulation, and slow rate (Duffy, 1995). To date, there is a marked lack of systematic, quantitative studies of voice changes in patients with Progressive Supranuclear Palsy.

Multiple Sclerosis

Multiple sclerosis (MS) is a progressive inflammatory neurodegenerative disease. The main pathology involves destruction of myelin and myelin-producing oligodendrocytes, which result in an accumulation of sclerotic plaques and impaired neural transmission. The destruction leads to multiple white-matter lesions throughout the brain stem, cerebrum, and cerebellum. As a consequence, a variety of symptoms can be observed ranging from motor and sensory disturbances to visual symptoms and cognitive impairments (Smith and McDonald, 1999).

Depending on the location of the lesions, patients with MS often present with a variety speech impairments. In general, the mixed form of dysarthria, including spastic and ataxic components, has been most often reported in MS. On a perceptual level, the most frequently observed characteristics of voice and speech were changes in loudness control, voice quality, articulation, emphasis, and pitch control (Darley *et al.*, 1972).

In an acoustic analysis of a sustained vowel phonation, voice samples of patients with MS were characterized by increased long-term phonatory instability, as measured by fluctuations of fundamental frequency and amplitude (Hartelius *et al.*, 1997). Temporal characteristic as measured by alternating motion rate (AMR) and sequential motion rate (SMR) tasks were shown to be a distinct features in MS patients. In general, voice samples of people diagnosed with MS were distinguished by longer gap duration and slower diadokinetic rate for both AMRs and SMRs, as well as longer syllable duration, observed in AMRs. In addition, analysis of energy characteristics revealed reduced vocal intensity in MS group (Tjaden and Watling, 2003). However, only a few attempts have been made to quantify the observed speech changes using systematic measurements such as acoustic analysis.

Acoustic Speech Characteristics in Psychiatric Diseases

Methods of acoustic quantification have also been applied to the speaking behaviors of persons with psychiatric disorders, most notably depression and schizophrenia. This avenue of research makes

inherent sense, as much depressive and schizophrenic symptomatology is assessed clinically using subjective rating scales designed to elicit verbal responses. Under these circumstances a number of rating items from which the clinical impressions are made are influenced by linguistic and paralinguistic aspects of the interview process. For example, in depression, the Hamilton Rating Scale for Depression (HSRD; Hamilton, 1980) guides the clinicians' judgment in rating depressed mood, psychomotor retardation, and anxiety based on subjective assessments of speech, voice, and communication. Similarly, the Positive and Negative Symptom Scale (PANSS; Kay, 1987) for schizophrenia contains a number of rating items related to speech and verbal behavior. Specific items related to clinical evaluation of the client's speech are found in the assessment areas of excitement, blunted affect, emotional withdrawal, poor rapport, lack of spontaneity and conversational flow, stereotyped thinking, motor retardation, disturbance of volition, poor attention, and preoccupation. Both the PANSS and the HRSD are considered gold standards for clinical assessment of their respective disorders, and the inclusion of such a large number of items related to spoken communication behavior indicates the pervasiveness of these traits in schizophrenia and depression.

Schizophrenia

Predominantly negative-symptom schizophrenia (NSZ) can be characterized by a number of atypical reductions in observed behavior, including communication behavior. Classically observed outward manifestations in spoken (e.g., linguistic production) and pragmatic/paralinguistic (e.g., body language, intonation, and prosody) aspects of communication are related to affective flattening, anhedonia, alogia, and avolition (the *Diagnostic and Statistical Manual of Mental Disorders* summarized characterization of NSZ), implying an effect on both affect and cognition. Atypical communication can have an effect on clinical assessment, as it may influence rater scoring on a number of items from subjective behavioral rating scales (e.g., PANSS) including items such as blunted affect, emotional withdrawal, poor rapport, social withdrawal, reduced flow of conversation, and motor retardation, to name a few (Alpert, 1996). Although these rating scales are invaluable in their ability to help clinicians assess symptomatology, the addition of objective and quantifiable measures of disease severity and therapeutic treatment response are desirable and possible through speech and voice acoustic measurement.

In the most basic terms, physical quantitative measurements of communication behavior, using aspects of frequency, intensity, and time, support and extend the clinical impressions of atypical communication used clinically (Alpert, 1996). This adds clinical value by providing repeatable quantification of observed symptomatology.

The literature surrounding acoustic investigations in persons with schizophrenia has revealed a number of consistent themes. Flat affect, alogia, and asociality (as measured by the PANSS scale) are strongly related to restricted speech output, monotonous speech, pause in speech, energy variation, utterance duration, and inflection (both in dB and Hz) (Dworkin, 1996; Alpert *et al.*, 1997, 2000; Puschel *et al.*, 1998). In addition, acoustic measures have shown great promise in identifying treatment response by demonstrating a larger treatment effect than those seen with traditional rating scales (Alpert, 1996). It has also been demonstrated that specific measures of acoustic inflection are sensitive enough to differentiate between antipsychotic compounds (Olanzapine vs. Haloperidol; Remoxipride vs. Haloperidol), whereas rating scales were not able to detect this difference (Alpert M, Smith R C, Pouget E R, Allan E, and Sisson C, unpublished data). Bidirectional changes in the speech acoustic characteristics between drug conditions have also led researchers to the conclusion that different mechanisms of drug action that may be at work, though rating scales were not able to make this distinction (Alpert *et al.*, unpublished data; Alpert *et al.*, 2002). Acoustic measures were able to separate the different drug groups at outcome while the rating scales failed to show a difference.

In a recent acoustic investigation in our laboratory, we have successfully demonstrated measurable differences in cognitive behavior and motor slowing by comparing persons with NSZ to a control group. Speech pause behavior in a simple counting and picture description task have indicated that average pause length was indicating of motor retardation, whereas global measures of pause were indicative of the increased cognitive linguistic demands of the picture description task. The analyses of longitudinal within-subject change data from this study are still ongoing.

Major Depression

The relationship between subjective estimates of the severity of major depression and observed qualitative or quantitative changes in speech production has been documented in a number of investigations. For example, Stassen *et al.* (1998) found a strong correlation between change in clinical ratings of symptom severity and several key voice acoustic measures. This finding was consistent in more than 74% of the researchers' patients undergoing inpatient

pharmacologic treatment for severe Major Depressive Disorder (MDD). Stassen *et al.* (1998) reported that fundamental frequency amplitude and mean pause duration were among the voice acoustic variables that most closely tracked with improvement in symptom severity, as measured by the 17-item HDRS (Hamilton, 1980) over the first few weeks of treatment. The former acoustic measure relates to the muscular and respiratory effort exerted to control phonatory intensity and rate, whereas the latter measure relates to motor timing and the execution of speech movements. These findings corroborate earlier reports that increased speech pause time and total speech time are associated with higher scores on the HDRS and other scales of psychomotor speed and subject self-rating of mood (Teasdale *et al.*, 1980; Hardy *et al.*, 1984). Longitudinal design studies by Ellgring and Scherer (1996) and Stassen (1998) have demonstrated similar results, using measures of speech rate, pause duration, and minimum fundamental frequency.

Regardless of the specific pharmacologic mechanisms of action of the antidepressant medications used in these studies, several speech acoustical measures consistently track with subtle changes in symptom severity. Moreover, these measures seem to be sensitive to early symptomatic improvement, as well as to the degree of response to drug intervention (Stassen *et al.*, 1998). The observed changes seen in these voice acoustical measures quite likely reflect changes in the modulation of both serotonergic and dopaminergic neurotransmitter systems in response to treatment of MDD. Previous literature supports the conclusion that two general aspects of speech and voice, specifically, motor timing and fundamental frequency, are closely related to mood states as measured by both subject self-report and clinician-administered rating scales (Stassen *et al.*, 1998).

The Clinical Utility and Application of Speech and Voice Acoustical Analyses

Acoustic correlates of neurological and psychiatric disorders have a realistic potential to provide complementary, sensitive methods for the early detection of the onset, progression, and severity of several disease states, as well as providing a means to objectively track symptomatic changes induced by therapeutic intervention (e.g., behavioral or pharmacological therapy, or both). There are no known risks related to the use of voice signal capture and analysis. On the contrary, a speech behavioral assessment may provide a rapid, nonintrusive, inexpensive, and relatively effort-free way to obtain objective data regarding disease progression and treatment response. It is noninvasive by nature, and in carefully controlled circumstances, it can provide a large amount of meaningful data. In addition, because altered communication ability is both bothersome and frustrating for so many patients who suffer from the diseases described above, the measurement of an improvement in speech quality is both desirable and encouraging for patients and families alike.

Despite the promising potential applications of this technology, the available literature on this subject remains equivocal and fraught with contradictory results. This variability in published results may actually reflect the high sensitivity of the measurements, the complexity of the speech production system, and the intersubject as well as intrasubject variability inherent in this type of research. Thus, there is a need for more normative data related to acoustical changes associated with neurodegenerative diseases, and improved consistency in methodology across laboratories, so that future results are more readily comparable.

Certain normative profiles have been recently provided in an article by Kent and colleagues (2003) and may help with enhancing the clinical utility of the acoustic analyses of voice disorders. Once the normative rules are applied in experiments across different laboratories, what today is perceived as conflicting results may in the future yield information about different aspects of the same disease. In summary, the acoustic analysis of voice is a research technique with great potential as a diagnostic tool for a variety of neurological and psychiatric disorders.

Speech Interface Design

J Lai, IBM Research, Hawthorne, NY, USA

The term 'speech interface design' refers to crafting a spoken interaction between a human and a computer. As humans, we are all familiar and comfortable with speech as a mode of communication. We 'interface' with other humans by speaking (using speech output) and by listening (using speech input). We call this interaction a conversation. When designing a speech user interface for a computer, the goal is to emulate a conversation convincingly enough that the person interacting with the computer can use what he or she has learned in a lifetime of conversations.

Designing a speech user interface is similar to designing any other interface for a human–computer interaction. A good design relies on using principles of user-centered design, and many of these same principles and techniques can be applied to speech interfaces. For example, it is important to know as much as possible about the people who will be using the application (the users) and to involve them in all stages of the design process. Once a prototype of the

new application is ready, it is important to test it with users and to iterate on the design. For general background information on user-centered design and usability testing, see Baecker and Buxton (1987), Nielsen (1993), Cooper (1995), and Preece *et al.* (2002).

Although there are similarities with other types of human–computer interfaces, speech interfaces have unique features. Because speech is such a familiar mode of communication for people, users have a certain set of expectations when speaking with a conversational partner. For a speech interface designer, the biggest design challenge is that people expect their conversational partner to understand the meaning of their words. Human listening is not just about decoding sounds; it is also about shared context and comprehension (Clark, 1993).

There are some excellent examples of speech user interfaces that are effective conversational partners. In these systems, the computer 'speaker' seems to remember contextual information and gives the impression of understanding what the user is saying. For example, several airlines use speech applications to handle telephone reservations or lost baggage tracking (Cohen *et al.,* 2004). These systems are a substantial improvement over previous interactive voice response (IVR) systems that relied solely on telephone keypad input. Instead of pressing 1 for this and 2 for that, users can speak natural language phrases, such as "I'd like to travel from Boston to New York." Speech applications have also been used effectively in situations where users' hands and eyes are busy. For example, a number of maintenance and repair applications have emerged, as well as applications to help people when sorting packages and doing other forms of other inventory management.

Not all speech applications are conversational in nature. Some are dictation systems that allow users to create typed text simply by speaking. These systems usually require some work on the users' part to train the system to recognize more accurately the sound of their voice. Although some dictation systems are intended for general text input (for example, typing a letter to your mother), others are tuned for specific domains, such as medical specialties (e.g., radiology) or legal dictation.

In general, it is effective to use speech applications for situations when a user's hands and eyes are busy doing another task. Likewise, speech input is useful when there is no keyboard available for text entry, such as when interacting with a computer over a telephone. Speech input is also a valuable means of interaction for people with certain types of physical disabilities that limit the use of their hands or for users who are not comfortable typing. Speech output is particularly liberating for people with visual impairments. In addition, it can be used to grab users' attention or to embody a particular personality for a computer system or character.

Although speech seems like it might be the ideal way to communicate with a computer at any time, there are situations when it is best not to use a speech user interface. For example, speech output is ineffective for delivering large amounts of information. Not only is it difficult for users to maintain the information in their short-term memory but people can also read much faster than they can listen. Speech input can also be problematic when the speaker is not in a private environment or when there are other voices in the background that might interfere with speech recognition.

The balance of this article addresses the steps necessary to design an effective speech interface. These steps include modeling the task the users will be accomplishing, listening to how they speak when accomplishing the task with another human, refining the task model, and selecting an appropriate technology. Once these steps are accomplished, the heart of the work for a speech interface designer is to design the dialogue – in other words, craft the prompts that the system will 'speak' and prepare the system for what the users will most likely say in response. Lastly, there should be a series of tests for the system, initially in the lab with users given a set of predefined tasks to accomplish, and ultimately out in a real-world environment with users accomplishing real tasks. In between the various forms of testing, a designer needs to allocate time to refine the design and make changes based on what is learned from the results of the testing.

Model the Task

The first step in a successful speech interface design is to model the task that will be enabled with speech technology. Modeling requires the designer to sketch out the logical steps that make up the task, along with the pieces of information that need to be exchanged to complete each step. With a speech application, each interaction between the system and a user is often referred to as a 'turn.' Thus, the 'task model' tries to capture the expected number of turns, as well as the vocabulary that is required to support the information exchange during those turns. It is important for the designer to take into consideration possible alternate flows because not all users approach the task in the same way. For example, when making a flight reservation, some users select a flight based exclusively on time schedules, whereas others

opt for airline loyalty and price points, accepting any flight time that meets their criteria for loyalty and price.

The model needs to operate within the set of constraints for the application. Constraints usually include the business goals for creating the speech application, as well as the requirements resulting from either the environment that users may find themselves in (e.g., noisy environment) or from the users themselves (e.g., the majority of users will be over 65 years old and uncomfortable with technology). For example, if one of the business goals is to cross-sell related items when a customer makes a purchase by calling into a speech-enabled call center application, the designer will want to incorporate a turn that involves the system suggesting related items that are on sale today.

Listen

After one has a rough model of the task, the next step is to educate oneself on how people talk in the domain of the task. One does this by listening to users who are doing an activity that is as close as possible to the target task. Keep in mind that the vocabulary and sentence structure used in graphical computer applications or in printed material may be quite different from the way people actually speak about a task. For example, imagine that you want to provide a speech interface to a calendar. Printed calendars and on-line calendars typically show day, week, and month views of calendar appointments. They always show days of the week and numbered dates. As soon as you listen to two people talk about appointments and scheduling, however, you learn that they only use numbered dates occasionally. The more common way to discuss dates with other people is to use relative descriptions: "What do you have a week from Monday? Are you busy this Thursday? What about the next day?" The concept of relative dates is completely absent from paper-based and on-line calendars; however, when speaking, users will expect to be able to use them.

With a little creativity, one can find or create situations in which two people can talk about the task for which one is creating a speech interface. Although one might want to plan out the interactions a little bit, care must be taken not to use scripts or memorized phrases. The goal of this type of listening is to allow people's natural social instincts to drive the dialogue. If at all possible, record the natural dialogues because they will serve as the basis for the speech interface design. Listening in this way is called a 'natural dialogue study.' Using natural dialogue studies, one can learn about the following:

- concepts used when talking about the task that are absent in other media
- common vocabulary used when talking about the task
- tone of voice that is considered polite in the context of the task
- sentence structure typical for the domain
- patterns of interaction
- methods people use to give one another feedback.

Refine the Task Model

With a sound understanding of how people speak in the domain of the application, the designer needs to go back to the task model and modify it based on what was learned from the natural dialogue studies. Doing so will most likely require adjustments to the vocabulary, as well as the flow for turn taking. In addition, the designer probably now has sufficient information about the types of users who will be interacting with the system to define a set of user characteristics. Some characteristics include comfort level with technology, frequency of interactions with the system, and motivation (e.g., entertainment, information browsing, or goal-oriented), as well as any additional user demographic information. When deciding on the general tone of the spoken application (e.g., financial applications should incorporate a more serious tone than a restaurant directory), the designer should consider the user characteristics, as well as the targeted platform for the solution (e.g., PDA, telephone, or cell phone) and the domain of the application. In most cases, the application will be designed to run on any telephone (land line or cell), and so the designer should focus on the harder of the two conditions, the cell phone, to make sure the application will run smoothly in this challenging environment for speech recognition. The designer will also have to decide whether to use a directed or an open-ended style for the interaction. The two most important factors that influence the style of the interaction are the type of system prompts that are written and the voice talent selected to record them.

Select the Technology

Although good interaction design in a speech application can compensate for certain shortcomings in speech technology (e.g., the lack of complete accuracy), if a certain baseline level of accuracy is not achieved, usually above 85%, the application will most likely not succeed. The level of accuracy depends on the choice of the underlying speech technology. As mentioned in the speech technology articles

(*see* **Speech Recognition: Statistical Methods**), speech recognition systems rely on three primary types of supporting files: an acoustic model, a vocabulary, and some form of grammar. In smaller command-and-control systems, such as a stock purchasing telephone application, the grammar is defined explicitly through a series of rules. For tasks that need to accept a much wider range of input – for example, software that supports dictation of medical reports – the 'grammar' is statistically defined and is referred to as a statistical language model (SLM). Because the input is more predictable, small-vocabulary grammar-based systems are more accurate than large-vocabulary SLM-based systems and thus should be used exclusively when working in challenging environments, such as noisy mobile phone usage. The advantage of a SLM is that it allows users greater flexibility in what they can say.

Another decision the designer will have to make is whether or not to allow barge-in. When barge-in is not enabled, the speech recognizer does not start listening until the end of the system prompt that is currently playing. If barge-in is enabled, it starts listening right away, and the user can interrupt the system at any time. Most systems these days support barge-in; however, because most users are not familiar with speech technology and are conditioned to think that interrupting speech is impolite (even if it is only a computer speaking), it is best to design natural pauses in long system prompts to give users the opportunity to interrupt without speaking over the prompt.

Whenever possible, it is a good idea to work with the speech technology vendor to ensure that the vocabulary, language model, and acoustic model accurately reflect the task, users, and environment. In most cases, the acoustic model cannot be modified without great cost and without making special arrangements with the vendor; however, the acoustic model is built with the intention of covering a wide range of situations. This is a good feature, because if only unaccented speech in a quiet setting was used to build the model, imagine the accuracy if it were used for workers who speak heavily accented English on a factory floor. In addition, the language model should be tuned to any particular phrasings used in the domain.

The last technology decision that the designer will have to make is whether or not to use any synthetic speech in the system. Synthetic speech, also known as text-to-speech (TTS), is speech produced by computer (*see* **Speech Synthesis**). Given that today's synthesizers still do not sound entirely natural, the choice whether to use synthesized output, recorded output, or no speech output is often a difficult one. Although recorded human speech is much easier and more pleasant for users to listen to, it presents a technical challenge when the information being presented is dynamic. For example, recorded speech cannot be used to read people their e-mail messages over the telephone. This is because the text is not known in advance and thus cannot be prerecorded. Most systems on the market today use recorded speech for system prompts that do not change and synthesized speech for dynamic text.

Design the Dialogue

The first step in designing a dialogue for a speech user interface is to review the data collected in the listen phase. Even an informal natural dialogue study provides a starting point for designing the four major components of the dialogue: prompts, input grammar for user commands, feedback, and error handling.

Prompts

Prompts are the instructions that the computer speaks to the user. A series of studies have shown that users unconsciously attribute personality traits to computers that speak, whether or not the designer intends for this to happen (Reeves and Nass, 1996; Cohen *et al.,* 2004). Given this factor, it is a good idea to design 'personality' into the dialogue from the outset. When designers consider the personality of the interaction, they make decisions about the wording of the prompts, the use of personal pronouns, and the sound of the voice that speaks the system prompts. The design should be dependent on the task and should be consistent with the brand experience one wants to present to users. Here are several sample prompts:

(P1) Computer: "Welcome to the ABC Bank-by-phone system where you can check your balance, pay a bill, or transfer money. Please say 'Check Balance,' 'Pay Bill,' or 'Transfer Money.'"

(P2) Computer: "Welcome to ABC Banking. Do you want checking, savings, or something else?"

(P3) Computer: "How can I help you?"

Because speech takes a long time to listen to, prompts need to be as short as possible to convey the necessary information. People are most likely to understand prompts if they do not use jargon and stick with the vocabulary, tone, and sentence structure observed in the natural dialogue study.

Prompts fall along a continuum from directed to open ended. Although speech manufacturers' literature often states that a directed dialogue is "a conversation with a goal," in reality, most directed dialogues

do not feel like conversations at all. With a directed dialogue, the system prompts direct the user what to say (hence, the name directed dialogue), as in (P1). Alternatively, a directed dialogue may be constructed like a form-filling application where the user is prompted for pieces of information to fill in the 'blanks' on the form. Here is an example of this style of interaction:

Computer: "Welcome to the Phone Travel Company. What city are you traveling to?"
User: "San Francisco."
Computer: "What city are you traveling from?"
User: "New York."
Computer: "On what day will you be traveling?"
User: "Saturday, May 6th."
Computer: "Around what time of day would you like to leave?"
User: "Around 5 p.m."

Open-ended prompts, such as "How can I help you?" (P3 above), invite users to speak a wider range of options. They enable more natural dialogues, but are also the most likely type of prompt to cause errors. People frequently will say things that the computer cannot understand. Often, the best tradeoff is to write moderately directed prompts, such as the second example (P2), which give users clear guidance about what to say, but still offer some degree of naturalness.

The type of interaction that is easiest for users and feels the most natural is a mixed initiative system. In this style, the system and the user take turns initiating the communication, depending on the flow of the conversation and the status of the task. With a mixed initiative system, the prompts can fluctuate between open-ended prompts and more directed prompts, depending on the context. If the user is encountering several speech recognition errors in a row, a good design will fall back to a constrained and directed style of interaction to move the conversation forward. When the consequence of the action is important – for example, when making money transfers or financial purchases – it is good to use a directed style to ensure that there is no ambiguity: "You wish to purchase 1000 shares of Omaha Mutual, please say yes or no."

Input Grammars

Once the computer has prompted a user, an input grammar governs what the computer can 'understand.' Grammars must be written in a formal grammar language that is dependent on the type of speech recognizer being used. If one is writing an application written in the Java (TM) programming language and using the Java Speech Grammar Format (Java Speech, 1998), for example, a snippet of an input grammar might look like this:

```
<command> = [<action>] <object> [please];
<action> = (I want) | (give me) | (let me have) | (go to);
<object> = ([my] checking [account]) | ([my] savings
   [account]) | (something else);
```

When faced with the second banking prompt (P2) above, the computer will be able to accept user commands, such as the following:

User: Checking please.
User: Savings account.
User: Let me have my checking account.
User: I want something else.

As the complexity of the grammar increases, so does the probability that the speech recognizer will make errors.

Feedback

Once the user has spoken a command, feedback is used to let the user know that the speech recognizer correctly decoded the speech (or not). Continuing with the banking example, feedback resulting from the user command, "Checking please," might be:

Computer: "Accessing checking."

It is common for feedback and prompts to be combined in order to move the dialogue forward as quickly as possible. For example:

Computer: "Accessing checking. Do you want balances, check history, or something else?"

Another important function of feedback is to let the user know if the computer is waiting for input or is busy processing input that it recently received. In conversations, timing is critical. People read meaning into pauses. Unfortunately, processing delays in speech applications often cause pauses in places where they do not naturally belong. For example, users may interpret a system silence, as they would in a human–human interaction, to mean that they were not heard or not understood. Doing so normally causes them to repeat themselves, which can lead to cascading problems in the interaction. It should be made clear to the user when the system is busy dealing with a request so that he or she does not speak again yet.

Error Handling

If the speech recognizer or the user does make an error, a well-designed speech user interface always

provides a way to correct the error. For example, an error correction grammar might be written to allow users to say things such as:

User: "Uh Oh!"
User: "Go back."
User: "That's not correct."
User: "No, I wanted savings."

The error correction strategy can also be explained in the prompt/feedback statement:

Computer: "Accessing checking. Say 'go back' if this is incorrect. [short pause] Do you want balances, check history, or something else?"

Error correction itself requires feedback so that the user knows that the error was acknowledged and corrected. For example, if the user says "go back," the feedback "sorry" might be combined with the more directed instructions on how to proceed:

Computer: "Sorry. Please say 'checking,' 'savings,' or 'other.'"

Usually, the command grammar is modified at this point to restrict input only to the exact words specified in the prompt to increase the likelihood of recognition success. Once the desired function is determined, the system could present the user with an example of a valid utterance.

Computer: "Would you like to buy, sell, or check stock prices?"
User: "I would like to sell."
Computer: "To sell a stock, you could say, for example: Sell 100 shares of GE at the market price."
User: "Sell 35 shares of Market Goods at the market price."

Test

Involving users throughout the design process of a speech application is crucial. A natural, effective interface can only be achieved by understanding how, where, and why target users will interact with the application. Testing early and discovering problems before too much effort has been put into the implementation saves time and money. Once a preliminary application design is complete, a wizard-of-oz study can help test and refine the interface. The speech data collected from this study can be used to help develop the grammar or, in the case of a natural language understanding system, to statistically train the engine on potential utterances. In these studies, a human wizard – usually using software tools – simulates the speech interface while interacting with users. In good wizard-of-oz studies, most users do not realize they are actually interacting with a human who is playing recorded responses. Major usability problems are often uncovered by these types of simulations.

Because computer tools are usually necessary to carry out a convincing simulation, wizard-of-oz studies are more time consuming and complicated to run than natural dialogue studies. If a prototype of the final application can be built quickly, it may be more cost effective to move directly to a usability study. A usability study assesses how well users are able to carry out the primary tasks that the application is designed to support. With speech applications, usability studies are particularly important for uncovering problems due to recognition errors, which are difficult to simulate effectively in a wizard-of-oz study, but are a leading cause of usability problems. Conducting such a study requires at least a preliminary software implementation. The application need not be complete, but some of the core functionality must be working. Usability studies can be conducted either in a laboratory or in the field. Study participants are typically presented with one or more tasks that they must figure out how to accomplish using the application. Additionally, the effectiveness of an application's error recovery functionality must ultimately be tested in the environments in which real users will be using the application. A good way to do this for telephone applications is to allow the new speech application to go live for a certain number of callers and to listen in on the interaction.

Final Tuning

Testing with real users accomplishing real tasks in a realistic environment will provide information that allows the designer to modify the grammar and prompts as necessary. Occasionally, live testing reveals that the wording of certain prompts consistently produces responses from users that were not predicted and thus are not modeled correctly in the grammar. Or, it could be that adjustments to the dialogue flow are necessary.

If testing goes on long enough to allow the same user to interact with the system more than once, it is useful to examine the log for significant differences between the first and second interaction to determine how much learning takes place or if each call is like a first call. If learning is taking place, the designer might want to include helpful hints on how to speak to the system, which can be removed over time. In addition, if users are hesitating before speaking or

after speech has been initiated, the amount of time to pause for silence detection can be increased.

Conclusion

Designing an effective speech user interface is an iterative process. Not even the most experienced designer will craft a perfect dialogue in the first iteration. To ensure that the system will be used over time, focus on users and do not be afraid to modify the design as new data are collected. Observe users during the task modeling phase to understand who they are and what are their goals. Listen carefully to users while conducting natural dialogue studies to determine how they speak in the context of the task. Test the design with target users to ensure that the prompts are clear, that feedback is appropriate, and that errors are caught and corrected. In addition, when testing, verify that the design is accomplishing the business goals that were set out to be achieved. If problems are uncovered during the test, revise the design and test again. By focusing on users and iterating on the design, one can produce an effective, polished speech interface design.

Introduction

When we listen to speech, our aim is to determine the meaning of the acoustic input. Only very rarely is a listener – usually some kind of speech scientist – concerned with the sounds of speech instead of with the content. Yet the study of speech perception has largely dealt with how listeners tell phonemes – the sounds of speech – from one another. Why is this so?

Phonemes are, by definition, the minimal units that distinguish between words, i.e., between one meaning and another. Listeners may know tens, indeed hundreds of thousands of words, and may still be able to learn new words effortlessly on a daily basis. However, languages construct this vast stock of words from, on average, only around 30 separate phonemes (Maddieson, 1984; see **Figure 1**). Thus, there is both parsimony and validity in the speech perception research program. Parsimony, because study of the perceptual cues to a few dozen phonemes is tractable in a way that study of the perceptual cues to individual words is not, and validity, because understanding how listeners tell, say, a /b/ from a /p/ informs us about the recognition of all word pairs that differ in these phonemes. It is important to realize that this research focus on cues to phonemic identity did not proceed from an assumption that phonemes necessarily played a role as units of speech perception. In fact, there have been many competing proposals concerning the basic unit of speech perception, all more or less unsatisfactory (Klatt, 1989), from units below the level of the phoneme (phonological features) to above it (diphones, syllables) to no sublexical unit at all. Rather, the phonemic research focus was the result of rational task analysis: to understand speech, listeners need to recognize words, and the process of recognizing words involves distinguishing a word from all other words that are its closest neighbors in the vocabulary – *word* from *bird*, *ward*, *work*, and so on. By making such distinctions, the listener

Figure 1 Distribution of phoneme inventory size across the representative sample of 317 languages analyzed by Maddieson (1984). The average number of phonemes is 31.

is effectively making decisions that are phonemic in nature.

True to the history of speech perception research, therefore, this review is organized first by phonemic category and the type of information that enables listeners to recognize members of each category; following sections deal with the principal theories that have driven speech perception research; and we conclude with a section on how this body of research relates to the recognition of the larger, meaningful units that really concern listeners.

Phoneme Perception

Phonemes in Real Speech

If words can indeed be viewed as a sequence of phonemes, it might seem reasonable to assume that these sounds are concatenated one after another in the speech stream. This is far from the case. Speech signals are continuous and it is hard to discern where one word ends and the next begins, let alone locate the borders of individual phonemes (see Figure 2). An analogy concocted by Hockett (1955: 210) still appears in most introductory textbooks: phonemes in speech are like colored Easter eggs moving on a conveyor belt to be crushed by a wringer. The wringer smears out the eggs so that no part of the conveyor belt is exclusively covered by the remains of one particular Easter egg. As a consequence, the coloring of one egg is mixed with the colorings of the surrounding eggs. This analogy is intended to convey that the speech signal is neither separable nor invariant. It is not separable because no part of the speech signal is exclusively influenced by one phonological unit. It is not invariant because adjacent – in fact even nonadjacent – phonemes are coarticulated, so that acoustic correlates of a given phoneme vary. Therefore, running speech is completely different from, for instance, Morse code, in which invariant acoustic signals are concatenated. In making this important point, the lack-of-invariance argument may sometimes be exaggerated. Some phoneme classes – for example, voiceless fricatives – can have quite salient and local cues (see the different tokens of /s/ in Figure 2). Others, however, show a great deal of variation. Stop consonants are a case in point; exactly the same stretch of speech can be heard as /p/ before one vowel, but as /k/ before another (see Figure 3). Vowels can also be highly coarticulated; thus the second formant (F2) in a vowel will generally be higher after alveolar consonants than after labial consonants, corresponding to the higher F2 locus in alveolar than in labial consonants.

Sources of variance arise both within and between speakers. Not only the phonetic context in which a phoneme occurs, but also the rate of speech and the speech register (from formal and careful to casual and careless) can affect how that phoneme is realized

Figure 2 An oscillogram and spectrogram of the sentence *This sentence is just for illustrative purposes* spoken by an adult male native speaker of British English born in Scotland.

within the utterances of a given speaker. So too can the degree of prosodic prominence within the sentence of the word in which the phoneme occurs. Variance between speakers arises most noticeably from physiological differences, e.g., in that the formant frequencies of vowels reflect the resonances of the vocal tract. The resonances are lower the larger the vocal tract; thus children produce higher formant frequencies than adults, and adults also differ. Further interspeaker variance is introduced by dialectal variation.

Variability may sometimes be so extensive that, superficially, a phonemic contrast is blurred. For instance, most languages that use nasals in word-final position allow the place of articulation to be assimilated to the place of a following consonant; the final consonant of *sun* may be pronounced /n/ in *suntan*, /m/ in *sunbathing*, /ng/ in *sunglasses*. In running speech, sounds may be deleted (e.g., the word *just* in Figure 2 contains no [t]) or inserted (an utterance of *something* may contain cues consistent with a /p/ between the two syllables, or an utterance of *pensive* may contain cues consistent with a /t/).

All of this variability makes the perception of cues to phonemes a nontrivial task for listeners. A large body of early speech research was dedicated to the search for invariant acoustic properties of phonemes. This enterprise may be reckoned unsuccessful with respect to its ultimate goal. Nevertheless, these efforts have certainly succeeded in finding acoustic properties, or cues, that correlate with certain phonemes or phoneme classes. This body of work represents a cornerstone of the study of speech perception and describes the basic cues for the recognition of phoneme classes and distinction within these classes.

Vowels Vowels are usually the parts of the speech signal containing local maximal amplitudes and periodicity caused by the vibration of the vocal folds. With these two cues, vowels can be reasonably well distinguished from consonants (see Figure 2). The vocal fold vibration gives rise to a periodic source signal with a large number of harmonics. This source signal is then filtered by the vocal tract (*see* **Speech Production**). The vocal tract amplifies some of the harmonics due to its resonance characteristics. Regions with amplified harmonics are called formants. The frequencies of these formants depend on the exact shape of the vocal tract, that is, on tongue position and shape, the position of the jaws, etc., (*see* **Speech Production**). Accordingly, vowels can be distinguished from one another by their steady state formant frequencies. The vowel system of a particular language is often presented in a two-dimensional vowel space with first-formant frequency on the ordinate and the second-formant frequency on the abscissa. This representation gives rise to a vowel triangle with the vowels [u] as in *shoe*, [i] as in *she*, and [a] as in *shah* as corners. Other vowels can be associated with different positions in this vowel triangle. Accordingly, listeners can identify vowels by computing the position in formant space (Nearey, 1989).

A number of facts complicate this simple picture. First, some languages also use diphthongal vowels, which are characterized by a formant movement throughout the vowel (as the vowel in *shy*). These diphthongs are usually contrasted to steady-state monophthongs, though categorization of vowels as either diphthongal or monophthong is in fact often difficult. Second, cues to vowel identity are also provided by duration – even in languages that do not distinguish long from short vowels – and by dynamic properties of consonant (C)-vowel (V) and VC transitions. Evidence for the importance of transitions comes from studies with so-called silent center CVC syllables, in which the steady-state portion of the vowel has been replaced by silence. Despite this

Figure 3 Two synthetic syllables with the same noise burst at the onset as used by Liberman (1996: Chap. 3). The two syllables are perceived as /pi/ and /ka/, that is, with different stop sounds, despite the identical noise burst.

gross mutilation of the vowel, identification accuracy is only slightly impaired. This cannot simply be attributed to a 'good-continuation' interpolation strategy over the silent part of the syllable that effectively restores the steady state, because silent-center syllables are still well identified if the onset and offset stem from different speakers. Instead, the dynamic consonant–vowel properties seem to carry higher-order invariants for vowel identification (Strange, 1999).

Sufficiency of one type of cue of course does not render other types of cue superfluous; it is clear that listeners can exploit both static and dynamic information in vowel perception.

Semivowels and Stops – Dynamic Consonants The classes of semivowels and stop consonants share the property of being defined by articulatory and hence formant movement. The labial stop [b] and labial glide [w] show similar formant transitions. The difference between the two sounds lies in the speed of the formant movement, which is faster for the stop than the semivowel. The semivowel [w] could be described as lying between the vowel [u] and the stop [b]; the stop has a fast rate of formant movement, the vowel has no or only a small amount of inherent movement, while the semivowel has a moderate amount of movement (Liberman, 1996: Chap. 6). Within the stop and semivowel classes, distinctions can be described by the concept of locus (Liberman, 1996: Chap. 5). Thus, [b] and [w] are associated with a labial place of articulation, while the corresponding [d] and [j] are associated with a alveolar place of articulation. Formant movements originate at the appropriate locus for each place or articulation, with especially the second and third formant being relevant for place distinctions. However, the actual onset of the formant frequencies will not be invariant (see Figure 2, with different formant-transition onsets in *purposes* for /pɜ/ and /pə/). The onset of the formant frequency is codetermined by the vowel. This has led to the concept of locus equations, which allow the place of articulation to be inferred based on formant-onset frequency and steady-state vowel frequency (see Sussman *et al.*, 1998, and the associated commentaries for strength and weaknesses of this concept).

Another well-studied distinction is the case of the voicing contrast for stops. English, for instance, contrasts voiced with unvoiced stops, as in *bath* versus *path*. The main cue for this distinction is voice-onset time (VOT). VOT is the temporal disparity between the onset of the opening of the vocal tract and the period movements of the vocal folds. The acoustic cues that arise as a consequence of this timing difference will be, in the case of a negative VOT (the onset of voicing then precedes the opening of the vocal tract), a 'prevoice bar,' a low-frequency hum. In case of a positive VOT, an aperiodic release burst is followed by aspiration. The exact location for which listeners switch from perceiving a voiced to a voiceless stop is language-specific, with some languages making a three-way distinction between prevoiced, unvoiced, and unvoiced aspirated stops.

Nasals and Fricatives – Static Consonants Nasals and fricatives share the attribute of having a stationary part. In Figure 2, which shows an example of running speech, six examples of [s] and one [n] can be seen. In all cases, a short but nevertheless reasonably stationary portion of the speech signal may be observed. Nasals are generally characterized by a

low-amplitude, low-frequency voiced signal (caused by an antiresonance; *see* **Speech Production**). Voiceless fricatives, in contrast, contain high-frequency noise. In the case of voiced fricatives, this noise is accompanied by a low-amplitude voicing. Within-class differences are signaled by spectral properties. For fricatives, lower fricative noises signal a more retracted place of articulation.

However, formant transitions in surrounding vowels also contribute to the identification of nasals and fricatives. For the case of prevocalic nasals, formant transitions in the vowel seem to be the most important cue. For postvocalic nasals and fricatives, the formant transitions become less important, while the importance of the steady-state spectral cues increases. The identification of nasals is, however, further complicated by reductions in running speech, such as assimilation, or deletion with nasalization of the previous vowel (as in the second nasal in *sentence* in Figure 2).

Laterals and Rhotics The recognition of laterals, e.g., [l] in the English word *lap*, and rhotics, e.g., [ɹ] in the English word *wrap*, is especially complicated. First of all, implementation of an /l/–/r/ contrast varies strongly across languages. In American English, the contrast is carried mainly by the frequency of the third formant. In Hungarian, the /l/–/r/ contrast is a contrast between a lateral and a trill, which is mainly carried by the presence or absence of amplitude modulation. While laterals can be defined phonetically, rhotics in different languages can be so different that some have retreated to the position that "the terms rhotic and 'r-sound' are largely based on the fact that these sounds tend to be written with a particular character . . . namely the letter 'r'" (Ladefoged and Maddieson, 1996: 215). This diversity is countered chiefly by the fact that these sounds seem to replace one another in related languages, or even in different accents of the same language.

In a given language, both /l/ and /r/ often vary in their pronunciation as a function of position in the syllable. Moreover, large interindividual sociophonetic and geographic variations are especially salient for these phonemes. Finally, the acoustic manifestations of the difference between [l] and [r] in English are particularly nonlocal. Reliable acoustic differences between words containing [l] and [r] may extend for more than one syllable to the left and right. As such, the perception of these segments proves to be a challenge for models that assume that spoken language must be recognized via identification of phonemes.

Trading Relations A list of cues to phoneme identity invokes an overly simple picture of speech perception: the perceptual system computes certain values, such as VOT, and then a language-specific mechanism applies simple rules such as (if [VOT $>$ 0.02s] $\Rightarrow$ voiceless). Alas, the speech signal is both too poor and rich to support such simple decision making. The signal is too poor in that, as described above, it lacks clear invariant properties that are reliably associated with a given speech sound. But secondly, it is also too rich, because a multitude of cues exist for each contrast. Consider the intervocalic voicing contrast in English *rabid* vs. *rapid*. Lisker (1986) lists no fewer than 16 cues to this distinction, including length of the preceding vowel, closure duration, and pitch contour. This redundancy partly compensates for lack of invariance, because information in one dimension can be 'traded' against information in another. Thus, a VOT more consistent with *rapid* may be over-ridden if the length of the preceding vowel strongly cues *rabid*. Note that it is in part due to this redundancy that a reasonably comprehensible signal may remain even after quite extreme deformation of the speech signal, for instance, silencing of the center of vowels.

Categorical Perception

As an empirical phenomenon, categorical perception is probably the most-oft replicated effect in speech perception. Consider the way in which the onset of the second formant crucially distinguishes [da] from [ba]. If in a sequence of synthetic syllables the second formant's onset frequency is varied continuously from a low [ba]-like value to a high [da]-like value, one should expect that listeners would report hearing the syllables becoming progressively more [da]-like. However, this is not what happens. Instead, listeners first report hearing token after token of [ba], and then suddenly change to reporting [da]. Only a small subset of stimuli is perceived ambiguously, that is, sometimes as [ba] and sometimes as [da] (see Figure 4).

In a classic experiment Liberman (1996: Chap. 10) evaluated both the categorization of such a continuum and the discrimination of sounds along this continuum in an ABX task (in which listeners hear three stimuli and decide whether the third is identical to either the first or the second). Listeners showed little ability to discriminate stimuli that were identified as the same phoneme, while they succeeded in between-category discrimination. This finding was of particular interest because it contrasts with the relation of identification and discrimination in other auditory perception domains. In pitch perception, for instance,

Figure 4 Illustration of categorical perception after Liberman *et al.* (reprinted in Liberman, 1996). The upper panel shows the stimuli 1–14, differing in the second formant transition. The middle panel shows the identification of the stimuli as either /ba/, /da/, or /ga/. The lower panel shows the results of a two-step discrimination task, in which stimulus one had to be discriminated from stimulus three. The figure shows that discrimination peaks coincide with category boundaries, but also that discrimination is generally better predicted by categorization.

discrimination performance exceeds identification performance: listeners can discriminate more than 1000 pitches, but have difficulty forming more than seven categories reliably. Moreover, the categoricality of perception was also found to disappear when formant transitions were presented without a vowel context. Consequently, there is no sharp discontinuity in perception, but each 'chirp' is perceived as equally different from neighboring members of the continuum. This finding further suggested that categorical perception was speech-specific.

Later findings, however, undermined this claim. For VOT contrasts, it has been shown that the boundary effects rest on discontinuities in auditory processing (*see* **Categorical Perception in Animals**). Moreover, the success of within-category discrimination is always better than chance, and more importantly, depends on the task and its implementation. The steepness of identification functions may, hence, be more aptly attributed to categoricalness at a decision rather than a perceptual level (see the chapters in Harnard, 1987).

The steepness of identification functions also varies with the speech contrast tested. Perception of vowels tends to be more continuous and within-category discrimination is easier to elicit. However, discrimination nevertheless seems more difficult if one of the two vowels to be discriminated is close to a prototypical vowel in a given language. This perceptual-magnet effect was supposed to be specific for speech perception (Kuhl, 1991). Later developments, however, cast doubt on the perceptual-magnet effect as such, and its specificity to human speech perception (e.g., Kluender *et al.*, 1998).

Two further findings in the categorical perception tradition indicate that the identification of a given stimulus varies with its environment (see the chapters in Harnad, 1987, for reviews). The first, an effect of the immediate environment of a speech sound, is called selective adaptation: an ambiguous stimulus between [ba] and [da] is perceived as [ba] if it is preceded by multiple [da]s, but as [da] if it is preceded by multiple [ba]s. This was explained by the assumption of specialized detectors for features that were subject to fatigue if repeatedly activated by an input; subsequent investigations, however, showed that adaptation can be explained by a combination of simple contrast effects with auditory adaptation. The second such effect, reflecting an influence of the larger-scale environment, is the effect of stimulus set range. If a stimulus set contains a good example of [ba] but only bad examples of [da], listeners will be more likely to identify intermediate stimuli as [da] than if the continuum ranges from a 'good' [da] to a 'bad' [ba]. Recently, a specifically lexically conditioned range effect has been discovered. Norris *et al.* (2003) exposed listeners to two lists of words and nonwords. One list contained some words ending in a 'good' [s] and other words ending with a 'bad' [f], while the other list contained words ending in 'good' [f] and a

'bad' [s]. Similar to the range-effect phenomenon, listeners exposed to the list with the 'good' [s] and the 'bad' [f] were more likely to perceive an ambiguous fricative as [f] than listeners exposed to the other list. In contrast to simple range effects, however, this only occurred if the unclear fricatives were embedded in words and not if they were embedded in nonwords. This indicates that lexical knowledge was used to shift the category boundary. Overall, these effects indicate that listeners have flexible phonetic boundaries, which can change based on influences of the immediate and the overall acoustic–phonetic context as well as based on lexical influences. The fact that languages change over time, and that pronunciation of speech sounds changes not only within a speech community but in the speech of individual members of the community (*see*), further underscores the flexibility of category boundaries.

Context Effects

Listeners' experience of variability in speech produces efficient compensation for variance-adding influences. Ladefoged and Broadbent (1957) presented test words embedded in the sentence *Please say what this word is* to listeners who had to decide whether the test word was *bit*, *bet*, *bat*, or *but*. A test word perceived primarily as *bit* in isolation was perceived predominantly as *bet* when presented in context of a carrier sentence with a lowered first formant. Thus, listeners judged vowels not only by their absolute formant frequencies, but also in relation to the formant frequencies in the surrounding words: if the test word was presented in the sentence with lowered F1, this as it were increased the perceived F1 in the test word, leading to the percept of a lower vowel. (Phonologically low vowels are associated with high F1 frequencies.)

Not only relational cues, such as formant frequencies in the surrounding words, but also intrinsic cues lead to such vowel normalization. For instance, f0 and higher formants may represent a frame against which absolute formant frequencies are evaluated. Other approaches argued for distance or ratio measures (e.g., [F1–f0] or [F2/F1]) as possible invariants over varying absolute values of formant frequencies. In a comparative study, Nearey (1989) showed that the strongest effects seem to be caused by relational properties, although – in keeping with the redundancy and multiple determination of speech perception – intrinsic vowel information also plays a role.

Compensation also occurs for within-speaker variation due to phonetic context. Lindblom and Studdert-Kennedy (1967) found that vowels with the same center frequencies were judged as more [back] – corresponding to a lower perceived F2 – in a [dVd] context than in a [bVb]. Similar effects have been observed for liquid-stop, fricative-stop, fricative-vowel, and vowel-nasal contexts (see Holt and Kluender, 2000 for a review). Likewise, compensatory influences have been observed for speech rate; a formant movement of a given duration is more likely to be perceived as [ba] if it is followed by a long vowel, as [wa] if it followed by a short vowel. A physically long vowel signals a slow rate of speech, so that a transition of a given length appears to signal a relatively shorter formant movement in such a context (Miller and Liberman, 1979).

Although these context effects impressively attest to listeners' ability to undo the introduction of variability in speech production, casual speech still holds sources of variance that challenge models of speech perception, such as segment deletions and reductions of phonological forms. Little is yet known about the perceptual resolution of such processes.

Theories of Speech Perception

The task of any theory of speech perception is to integrate the facts of segment perception as just laid out into a coherent framework. Two questions have been central for theories of speech perception. First, is there an innate specialization for speech perception that sets it apart from 'ordinary' auditory perception? Second, does speech recognition take speech production into account? In a certain way, the answer to the second question has to be yes. Speakers and listeners communicate efficiently, which necessarily implies that the listeners can make sense of the production mechanisms. Theories differ as to whether this parity between speaker and listener also implies that the listener takes into account the mechanism that produces speech in speech perception.

Motor Theory The motor theory of speech perception holds that speech is perceived via recognition of the speaker's intended phonetic gestures. Developed at Haskins Laboratories during the 1950s and 1960s by Liberman and colleagues (see Liberman, 1996: Chap. 1), the theory arose from the team's findings that percepts evoked by speech sounds seemed not tightly coupled to acoustic properties. However, there was correspondence to articulatory gestures; thus uniting the onsets of [ki] and [ku] was the fact that in both cases the tongue body obstructs the airflow in the back oral cavity. Articulatory measurements indicating that speech gestures themselves depend strongly on context resulted in later versions of the theory positing a more abstract invariant, the neural commands that initiated articulation.

According to motor theory, speech perception depends on a specialized module that is part of humans' biological endowment for language, not dissimilar to the echo-location ability that enables bats to navigate in the dark. This module captures all auditory stimuli that seem linguistically relevant before 'ordinary' auditory percepts arise. The module uses an internal speech synthesizer to determine which motor commands are most likely to account for the speech input, a process called analysis by synthesis. Such a mechanism can account for the context dependencies and trading relations described above; the internal synthesizer produces the same dependencies in its resynthesis attempts as occur in natural speech. Due to the emphasis on speech gestures, motor theory also accounts naturally for the influences of visually perceived speech on speech perception (*see* **Audio-visual Speech Processing**).

Additional evidence for motor theory comes from studies that indicate a difference between speech and nonspeech perception. The phenomenon of categorical perception was therefore an important finding for early motor theory. Another effect held to show that 'speech is special' is duplex perception; if the formant transitions of the second and third formants of a CV syllable are presented to one ear and the rest of the syllable to the other, the syllable is perceived as an integrated whole. These formant transitions are heard as nonspeech chirps, just as in isolation; nevertheless, they can be integrated with the rest of the syllable to determine whether the syllable is perceived as, say, [da] vs. [ga]. The signal is effectively heard twice, as speech and as nonspeech (hence the term **du**plex perception). An auditory theory might account for an integration of the signals at both ears, but would seem to predict a triple percept, of each of the two parts separately plus the integrated percept. Duplex perception seems to be better accounted for by a distinction between speech perception and auditory perception.

Motor theory's claim that such phenomena are unique for speech perception and/or human listeners is, however, hard to maintain. With respect to categorical perception, within-category discrimination is often possible, and the sharpness and most probable location of category boundaries seem to be shared between human and nonhuman listeners. Context effects, trading relations, and duplex perception have been observed with nonhuman listeners and/or nonspeech sounds. Such observations do not, of course, contradict the assumption that speech perception rests on specialized mechanisms. The auditory abilities of nonhuman listeners may indeed allow some speech perception, but this does not imply that human listeners perceive speech by the same means. However, positing a very powerful innate speech analyzer is unparsimonious. Further, motor theory suggests that the neural substrate for speech perception differs from that for nonspeech perception. If the capture of a sound by the speech-perception system prevents alternative auditory perception, this module should be located early along the auditory neural pathway. Current investigations, however, indicate a great overlap of speech and nonspeech perception in terms of neural substrate in these early cortical areas (Scott and Wise, 2004).

Direct-Perception Theory The theory of direct perception of speech (e.g., Fowler, 1996) also maintains that the perception of speech is tightly linked to production mechanisms. Based on Gibson's theory of direct perception, the theory holds that perceptual systems have evolved to perceive the sound-causing structures directly using higher-order invariants. A well-known example of an higher-order invariant is a cue for size in vision: an object on a checkered surface covers the same number of squares whatever the distance between observer and object. Similarly, the movements of the articulators are supposed to give rise to higher-order invariants that allow them to be perceived directly. Thus, the direct-perception theory and motor theory both assume that the perceptual system recovers speech gestures from the signal. However, in the direct-perception theory this is achieved without an innately specified speech synthesizer.

By referring to articulation, direct-perception theory accounts for context effects and trading relations in the perception of speech just as motor theory does. According to the direct-perception account, the evidence that motor theorists hold to show a perceptual difference between speech and nonspeech is actually an effect of meaningfulness. The nonspeech sounds under investigation were not environmental sounds, as speech is, but meaningless constructed sounds. The importance of ecological significance of the sounds under investigation was buttressed by the finding that duplex perception occurs for meaningful nonspeech sounds such as a slamming door (see Fowler, 1996). Given that the direct-perception theory does not argue that speech is special, evidence for human-like perception of speech by nonhuman species is not problematic for the theory.

To distinguish direct-perception theory from more general accounts (see below), it is necessary to show that speech-perception phenomena cannot be accounted for by either an auditory or general learning explanation. One piece of such evidence derives from the multimodality of speech perception. The McGurk effect (*see* **Audio-visual Speech Processing**) shows

integration of auditory and visual speech, and similar integration arises when perceivers hear and feel – with their hand on the lips of a speaker – a syllable. Just as with visual speech, haptic speech codetermines the ultimate percept. The absence of opportunity to learn the association between felt and heard gestures – we rarely touch each other's lips during conversation – speaks against a general learning account and by implication in favor of the direct-perception account. The principal weakness of the direct-perception account, however, is that it is questionable that higher-order invariants indeed specify speech gestures; little progress has been made in underpinning this part of the theory.

General Auditory and Learning Account The assumption that speech perception relies on general auditory and perceptual-learning abilities (Diehl *et al.*, 2004) is more a framework than a theory. This approach denies specialization for speech perception and excludes reference to production in perception. The challenge for this approach is to account for the exquisite attunement of listeners to the dynamic properties of speech production; it is addressed by reference to evidence of perception-based constraints on production (see, e.g., Ohala, 1996). Despite large differences across languages in the size of vowel inventories, for example, vowel systems seem to place vowels in the vowel space so as to maximize perceptual distance, and hence minimize confusability between vowels. Motor theorists' arguments that the structure of phonetic categories – with a large number of potential cues, each individually unreliable – can only be captured by reference to production is countered by pointing out that categories without invariant features are not unique to speech (consider Wittgenstein's category *game*). Context effects, likewise, are not unique to speech perception, but are typical for perception in general. For some context effects and trading relations, auditory processing seems indeed to be sufficient (*see* **Categorical Perception in Animals**).

From Phonemes to Words

To arrive at an utterance's interpretation, listeners must in effect segment the continuous input and identify the sequence of individual words comprising it. These two processes are interdependent.

Segmentation

Word boundaries in running speech are similar to phonetic categories in that there is no reliable acoustic cue analogous to the white space which marks word boundaries in written text. In Figure 2, there are three visible pauses. All of these pauses occur in front of voiceless stops, and in only one case (the onset of *purposes*) does the pause correspond to a word boundary. Even worse, the word boundary between *this sentence*, does not even coincide with a phoneme boundary, as the two occurrences of /s/, before and after the word boundary, are produced as a single geminate fricative. However, just as phonetic categories make up for the lack of invariance by a large number of potential cues, there are multiple, in large part language-specific, cues to word boundaries.

A first class of cues is physically 'in the signal' and based on fine phonetic detail. For example, voiceless stops in English are generally unaspirated, but in word-initial, position will be aspirated. Figure 2 provides an example with a longer VOT for the first /p/ in *purposes*. Listeners can hence distinguish, for example, *ice cream* from *I scream* based on the phonetic properties of the [k]-sound. Embedded words, such as *cap* in *captain*, may also be recognized on the basis of fine phonetic detail: f0 contour and duration of the syllable [kæp] differ between instances of the intended one-syllable and two-syllable word. This type of effect constrains the possible architecture of prelexical processing: the fine phonetic detail must be retained in order to allow subphonemic detail to influence lexical segmentation (see McQueen *et al.*, 2003).

Currently, there are at least three accounts for how phonetic detail is used. First, an episodic account assumes that there are no prelexical units, but that the lexicon consists of episodic traces of words. For the case of embedded word, a *cap* from *captain* will not produce a good fit with the episodic traces stored for occurrences of the word *cap*. Second, an allophonic model would postulate different phoneme-sized prelexical units for different instances of the same phoneme, depending on position within a syllable. Finally, a prosodic account proposes that fine phonetic detail in f0 and duration are subject to a prosodic analysis, which is used to guide segmentation. Note that the last two accounts are not necessarily competitors, but may capture different, temporal and spectral, aspects of fine phonetic detail.

A second class of cues to word boundaries is statistical in nature. Phonotactic constraints prohibit certain sequences syllable internally (e.g., /mr/ cannot occur syllable internally in English or Dutch). Other sequences are probabilistically associated with word boundaries (e.g., many words or few words begin in such a way). Moreover, such cues need not be restricted to adjacent phonemes: vowel harmony cues in languages such as Finnish can indicate to listeners where word boundaries occur. All such cues are

language-specific, as also are the rhythmic cues that listeners use to segment speech (stress rhythm in stress languages, etc.). Listeners are able to exploit all these types of boundary cues (see McQueen and Cutler, 2001).

Finally, lexical competition also contributes to segmentation. Consider the utterance *ship inquiry*. The first two syllables correspond to the word *shipping*, the next to *choir*. This, however, leaves *y* unaccounted for. This parse would be prevented if word candidates compete for activation, and this competition also influences word segmentation. Then, both *ship* and *inquiry* would inhibit the candidate *shipping*, while the parse *shipping* and *quiry* would only contain one lexical candidate that may inhibit activation of other items. All current models of spoken-word recognition incorporate some such process (*see* McQueen and Cutler, 2001, and **Speech Recognition: Psychology Approaches**).

Models of Spoken-Word Recognition

Models of word recognition aim to account for the retrieval of long-term memory information given the perceptual input. There is consensus on at least three issues: activation, parallelism, competition. All models make use of the activation metaphor: word candidates can be activated in a graded fashion. In contrast to look-up from a printed dictionary, the process is not a one-to-one search and comparison between input and stored knowledge, but instead multiple word candidates are activated in parallel. Activated candidates then compete for recognition. The models differ on many issues of architecture, which are discussed in more detail in **Speech Recognition: Psychology Approaches**.

In what follows, we give a short impression of existing models of spoken-word recognition. Each model has its specific merits and weaknesses, as the models differ in their primary motivation. This makes the models partly incommensurable. Models can be compared, however, with respect to their basic units and assumptions.

TRACE TRACE (McClelland and Elman, 1986) assumes that speech input activates phonetic features, which in turn activate phonemes, and these in turn activate word nodes. These three levels are linked by facilitatory connections in both directions. Thus, the feature 'nasal' activates the phoneme nodes [n], [m], and [ng]; the phoneme node [n] activates the word node for *neat*, *nose*, *narrow* etc. Once a word is sufficiently activated, facilitation can flow from the word node back to the phoneme nodes for each segment in the word. Within each level, candidates (features, phonemes, or words) compete with one another via inhibitory connections. TRACE was the first model to posit such an active process of inhibition between word candidates. The most controversial aspect of TRACE is, however, the assumption of facilitating top-down connections from lexicon to prelexical nodes. This form of feedback, however, does not seem to be functional (facilitation flows from the most activated word candidate; as this word is already most activated, it needs no further assistance to win the competition; Norris *et al.*, 2000) and the behavior of the model does not crucially depend on the top-down connections.

In order to account for time invariance, TRACE duplicates the phoneme and word level multiple times. Thus, [n] in the nth 'input slot' activates *nose* in the lexicon aligned with the nth slot, *ant* in the lexicon aligned with the (n–1)th slot, and so on. This solution of the time invariance problem necessitates a forbidding number of connections between word nodes, because every word node is duplicated multiple times and has inhibitory connections to all other word nodes. In consequence, modeling with TRACE is only tractable with a small lexicon.

Shortlist Shortlist (Norris, 1994) models word segmentation and recognition in continuous speech, and allows simulations with a realistic lexicon of tens of thousands of words. These features probably make it the most complete model of word recognition. In its current form, the model's weakness is that it relies, as a simplifying assumption, on a phonemic input pattern.

The model assumes that word units are activated by match with bottom-up input and inhibited by bottom-up mismatch, thus accounting for evidence that even in long words, phonological mismatch in one segment can have powerful effects (Norris *et al.*, 2000). Shortlist differs from TRACE both in this utilization of mismatch information and in the absence of top-down feedback.

Once a number of candidates are activated, a shortlist of candidates is generated, and these are wired into a purpose-built interactive-activation network, where inhibitory connections between candidates induce competition. In order to achieve segmentation, the model uses, besides the competition, attested constraints and perceptually relevant cues to word boundaries (see 'Segmentation').

MINERVA2 Goldinger's (1998) model of an episodic, exemplar-based lexicon assumes no prelexical level; in consequence, the question of feedback does not arise. The episodic lexicon consists of episodes of words in which a 'name' part of a given episode was assumed to be invariant, while other parts encoded

varying situational contexts and voices. A given stimulus causes different traces to resonate depending on overlap with the input. If multiple instances of the same word have been presented before, the echo will be relatively 'abstract': multiple traces differing in voice and context information will be activated, with voice and context activations canceling each other out. If only a few episodes are available, the echo will entail a large amount of voice and context information. The model accounts well for the amount of phonetic detail that listeners replicate in repeating speech: more phonetic detail is retained for low-frequency words, or nonwords presented only rarely in a training phase, than for high-frequency words, or nonwords presented often in training.

One weakness of the model is that it claims to be a model of word recognition without speaker normalization. In its current form, however, speaker and word information are completely separated in memory. Given that both vowel identity and speaker identity determine, for instance, formant values in vowels, the model implicitly assumes a prelexical level at which vowel identity and speaker identity influences on the speech signal are distinct. This separation is exactly what normalization achieves, and hence the input to the model is not more realistic than the input that is used to drive models involving normalization.

Neighborhood Activation Model The neighborhood activation model (NAM) (Luce and Pisoni, 1998) allows specific predictions of competition between word candidates. In its current form(s), the model is severely limited by being implemented only for words with three segments. It assumes a prelexical processing stage with allophonic recoding of the acoustic input without activating feedback from a lexical level.

The model incorporates a recoding process in which a string of segments as initial input is fed through a known confusion matrix established for CV and VC syllables. This gives rise to graded activations of multiple allophone candidates for every segment, and accordingly, to the activation of multiple candidates. Not only the target word itself is activated, but also its phonetic 'neighborhood.' This allows the model to account for evidence from phonetic priming experiments for similarity-based activation and inhibition. The dynamics of the competition process depend on the neighborhood density and the balance of the frequency of the target word and its neighboring competitors. Lexical selection is achieved by a choice rule that takes into account the (frequency-biased) pattern of activation across the competitor set.

Distributed Cohort Model The distributed cohort model (DCM) (Gaskell and Marslen-Wilson, 1997) is currently the only model that relates phonological and semantic representations (though this topic has attracted considerable attention in theories of speech production, *see* **Spoken Language Production: Psycholinguistic Approach**). It posits phonological feature values presented in serial fashion as input, these to be processed by a recurrent network and mapped onto distributed patterns in the lexicon.

Different lexical knowledge domains, namely semantics and phonology, are represented in parallel. Competition between word candidates arises not through lateral inhibition, but because of limited capacity in the lexical networks. Words are not represented by word nodes, but different words make use of the same units in the semantic and phonological networks. It follows that the dynamics will be different in the phonological domain than in the semantic domain. While representations in the phonological domain slowly converge on the phonological representation of a word as it unfolds itself, the semantic network shows a more chaotic behavior. This is a consequence of the fact that words such as *captain* and *captive* share phonological features but have little semantic overlap.

Adaptive Resonance Theory From the framework of adaptive resonance theory (ART), a number of models have been proposed that deal with word recognition and segmentation (e.g., Grossberg and Myers, 2000), though no model with a large vocabulary based on this framework has been presented to date. ART assumes that recognition depends on the development of a resonant cycle between word-level representations and prelexical representations. This involves online feedback from the lexical to the prelexical level activating the corresponding phoneme units, which in turn activate the lexical unit. The nature of this feedback is, however, different from that in TRACE. Here the resonance is crucial because lexical nodes cannot reach more than subliminal levels of activation without it.

The model is able to accept either features or phonemes as input. It uses no 'slots' for the input; input is presented in continuous time. In principle, this should allow ART to capture the role of temporal detail in the segmentation and competition process.

Summary

Our understanding of the human perception of speech sounds and recognition of words has grown considerably over the last decades and will continue

to grow. It has become apparent that phoneme perception exploits multiple and diverse cues, and draws on immediate and distant acoustic–phonetic context. However, the recognition of speech sounds is probably not achieved without some uncertainty, and as a consequence, the recognition of words entails the activation of multiple candidates that compete for recognition.

At the same time, basic issues have not been resolved. Do we perceive speech as sound or as gestures? Is there a prelexical unit that is used to access the lexicon, and if so, what form(s) should it take? Does the lexicon contain abstract information, or does it consist of a multitude of concrete episodes? The differing theories can be aptly described as research programs that are difficult to compare. Significant progress may be achieved if, for instance, abstractionist models try to account for the evidence that motivates episodic models – exquisite memory for phonetic detail – while episodic models address the evidence that speaks for normalization and for generalization of phonetic knowledge across words. Hybrid models that can account for both these sets of evidence may set the tone for the next generation of word perception models. In the domain of phoneme perception, gestural theories have to address the question of how gestures can actually be perceived, while a more general account needs to accumulate constraints in order to become more testable.

Speech Processes in Dysarthria

F R Boutsen, University of Oklahoma, Oklahoma City, OK, USA

© 2006 Elsevier Ltd. All rights reserved.

In an era when the terms 'speech' and 'language' were used interchangeably, and Broca and Wernicke's constructs of 'aphemia' and 'aphasia symptom complex' found harmonious reconciliation in localizationist theories of language, Kussmaul (1881) broke tradition by asserting that the seat of speech is most likely not confined to a cerebral convolution. Furthermore, unlike his contemporaries, he drew a clear distinction between the neurological disorders of speech and language. In what is conceivably the first classification of neurogenic communication disorders, he defined as separate from aphasia a group of articulation disorders that were due to organic or psychic disturbances of the central nervous system (CNS). These articulation disorders he labeled dysarthria, which were to be distinguished from the dyslalias that resulted from peripheral lesions and/or malformations of the articulators or the cranial nerves (Grewel, 1957).

Overall, Kussmaul's broad neurological roadmap, albeit provocative for its time, did not much more than delimit the concept of dysarthria, confining it to the CNS apart from language and functional/organic speech disorders. It was not until later that more refined neurological classification schemes began to also assert a coupling between the still fairly amorphous dysarthria symptom complex and etiologies that were bound within levels or components of the central nervous system. For example, Zentay (1937), Froeshels (1943), and Luschsinger and Arnold (1949) classified the etiologies associated with dysarthria at four levels within the central nervous system (the corticobulbar, cortico-strio-pallido-rubro-bulbar, frontopontine, and cerebellar levels). Growing consideration of speech processes, other than 'articulation,' as well as a broadening array of 'dysarthric' symptoms needing theoretical cover, soon stretched and refined the four-level classification schemes to include the peripheral nervous system (PNS) and subdivisions within the neuroanatomic levels. The classifications of Peacher (1950) and Grewel (1957), perhaps, best embodied this trend. In seminal papers, these authors formulated what even by today's standards can be regarded as a modern neurological perspective on dysarthria.

Peacher and Grewel defined dysarthrias, with the exclusion of developmental, somatic, or psychogenic speech disorders, as disturbances of the speaking system resulting from neurological disorders that involve the cortical, subcortical, brainstem, and spinal levels. Physiologically, the aforementioned disorders were proposed to yield distinct motor deficits that in turn patterned different dysarthria types. Those enumerated in Grewel's theory included dysarthrias associated with flaccid or spastic paralysis, rigidity, discoordination, lack of sensation, difficulty with praxis, and disinhibition (as seen in echolalia).

Though conspicuous in some places of their theory, the objective to link the varied phenomenology of dysarthria to neuroanatomical levels was not the sole organizing principle in either of the aforementioned frameworks. This is because the proposed divisional lesions of the nervous system that they argued were capable of framing a dysarthria type were also undergirded by views concerning the neuroanatomical levels of the 'normal' speech mechanism if not the various processes that partake in it. The theoretical requirement that a neuroanatomical map of dysarthria would be consistent with that underlying normal speech processes was perhaps most strongly articulated by Peacher (1950). He argued that while clinically, it might be anticipated that dysarthria presents varying degrees of dysfunction in articulation, phonation, resonation and respiration, speech rhythm needs inclusion as well. He felt its incorporation was justified in view of normal speech data reported by Stetson (1932) who had shown that

Speech Processes in Dysarthria

F R Boutsen, University of Oklahoma, Oklahoma City, OK, USA

In an era when the terms 'speech' and 'language' were used interchangeably, and Broca and Wernicke's constructs of 'aphemia' and 'aphasia symptom complex' found harmonious reconciliation in localizationist theories of language, Kussmaul (1881) broke tradition by asserting that the seat of speech is most likely not confined to a cerebral convolution. Furthermore, unlike his contemporaries, he drew a clear distinction between the neurological disorders of speech and language. In what is conceivably the first classification of neurogenic communication disorders, he defined as separate from aphasia a group of articulation disorders that were due to organic or psychic disturbances of the central nervous system (CNS). These articulation disorders he labeled dysarthria, which were to be distinguished from the dyslalias that resulted from peripheral lesions and/or malformations of the articulators or the cranial nerves (Grewel, 1957).

Overall, Kussmaul's broad neurological roadmap, albeit provocative for its time, did not much more than delimit the concept of dysarthria, confining it to the CNS apart from language and functional/organic speech disorders. It was not until later that more refined neurological classification schemes began to also assert a coupling between the still fairly amorphous dysarthria symptom complex and etiologies that were bound within levels or components of the central nervous system. For example, Zentay (1937), Froeshels (1943), and Luschsinger and Arnold (1949) classified the etiologies associated with dysarthria at four levels within the central nervous system (the corticobulbar, cortico-strio-pallido-rubro-bulbar, frontopontine, and cerebellar levels). Growing consideration of speech processes, other than 'articulation,' as well as a broadening array of 'dysarthric' symptoms needing theoretical cover, soon stretched and refined the four-level classification schemes to include the peripheral nervous system (PNS) and subdivisions within the neuroanatomic levels. The classifications of Peacher (1950) and Grewel (1957), perhaps, best embodied this trend. In seminal papers, these authors formulated what even by today's standards can be regarded as a modern neurological perspective on dysarthria.

Peacher and Grewel defined dysarthrias, with the exclusion of developmental, somatic, or psychogenic speech disorders, as disturbances of the speaking system resulting from neurological disorders that involve the cortical, subcortical, brainstem, and spinal levels. Physiologically, the aforementioned disorders were proposed to yield distinct motor deficits that in turn patterned different dysarthria types. Those enumerated in Grewel's theory included dysarthrias associated with flaccid or spastic paralysis, rigidity, discoordination, lack of sensation, difficulty with praxis, and disinhibition (as seen in echolalia).

Though conspicuous in some places of their theory, the objective to link the varied phenomenology of dysarthria to neuroanatomical levels was not the sole organizing principle in either of the aforementioned frameworks. This is because the proposed divisional lesions of the nervous system that they argued were capable of framing a dysarthria type were also undergirded by views concerning the neuroanatomical levels of the 'normal' speech mechanism if not the various processes that partake in it. The theoretical requirement that a neuroanatomical map of dysarthria would be consistent with that underlying normal speech processes was perhaps most strongly articulated by Peacher (1950). He argued that while clinically, it might be anticipated that dysarthria presents varying degrees of dysfunction in articulation, phonation, resonation and respiration, speech rhythm needs inclusion as well. He felt its incorporation was justified in view of normal speech data reported by Stetson (1932) who had shown that

speech rhythm was 'peripherally' dependent on the respiratory cycle. He further cited clinical evidence including Monrad Krohn's (1947) observation of 'dysprosody' in extrapyramidal disorders as well as the well-known failure of rhythm to develop in the congenitally deaf.

While Peacher assigned a critical role to the 'peripheral' processes of audition and respiration in speech rhythm, he also hypothesized this function to be dependent on integrative functions, which, like those for speech, if disturbed produce deficits that are to be distinguished from dysarthria. Here Peacher's general account of the speech process as well as his classification differs from that of Grewel. Borrowing from Froment (1924), Grewel conceived speech to unfold in two successive stages: that of praxis and that of execution. This latter process, defined as the release of a series of reflexes, was dependent on intact sensibility and required coordination of the successive stages of the speaking procedure (respiration, phonation, articulation). Along these lines, Grewel, unlike Peacher, defined, as was shown above, apraxia of speech as a subtype, albeit at the margins, of dysarthria. In addition, in further contrast with Peacher, Grewel accorded the (integrative) processes of attention and memory a more penetrating role in speech. In his view, disturbance in these processes could complicate the dysarthric symptoms.

Finally, apart from these theoretical differences, Peacher and Grewel both claimed that a neurological perspective on dysarthria lacked diagnostic power and therapeutic relevance if it was not also complemented by detailed speech analysis. In this regard, they proposed some procedural guidelines for the diagnosis of dysarthria and provided an initial broad description of the speech symptoms in the various dysarthria types. Even so, realizing that descriptions of dysarthric speech were subjective and at best impressionistic, Peacher (1950) called for a resurveying of the entire field using principles of experimental phonetics and speech pathology.

Though not yet employing an experimental method, Darley *et al.* (1969a, 1969b) attempted to do just that in the first systematic and comprehensive study of the audible characteristics of the dysarthrias. The raw data in this investigation comprised reading samples of 212 patients with dysarthria whose neurological diagnosis fell in one of seven categories: pseudobulbar palsy, bulbar palsy, amyotrophic lateral sclerosis, cerebellar lesions, parkinsonism, dystonia, and choreoathetosis. These neurological disorders were a likely choice, as they had been the subject of earlier dysarthria investigations in some form or another. Listening to the tapes, Darley and his colleagues tried to capture the distinct phenomenology of the dysarthrias, not within neuroanatomic levels as had been done before, but within the audible domain. Toward this goal, they conceptualized a series of speech and voice dimensions along which to rate the speech samples. These dimensions were not inspired by a phonetic or prosodic theory, but rather by the requirement that they could be more or less directly perceived, reflect a minimum of interpretation and data reduction, or in other words had high face validity. A direct consequence of this phenomenological approach was that prosodic processes such as coarticulation, resyllabification, syllable lengthening/shortening, and pitch declination remained largely outside the scope of the analysis. Also, similar to what occurred in the neurological perspective on dysarthria before, the initial set of dimensions quickly had to be expanded to more fully capture the diverse universe of the audible symptoms in dysarthria.

Ultimately, Darley *et al.* settled for 38 dimensions along seven major categories. They included pitch (level, breaks, tremor, or mono), loudness (level, decay, alternating, excessively varied, or mono), vocal quality (harsh/wet hoarseness, continuous/transient breathiness, strained voice, hypo/hypernasality, and nasal emission) audible aspects of respiration (forced inhalation or exhalation, audible inspiration, grunt at end of expiration), prosody (rate, short phrases, increased overall/segmental rate, variable rate, reduced/excessive stress, silences, short rushes of speech), and articulation (imprecise consonants, vowel distortion, prolonged/repeated phonemes, irregular articulatory breakdown). In addition, speech samples were rated along two overall dimensions: intelligibility and bizarreness. Overall, it can be seen that apart from the general impression dimensions, the perceptual categories rated by Darley *et al.* tapped dysfunction(s) along more or less the same major components/processes of speech, as were outlined within the neurological perspective on dysarthria.

The results of Darley *et al.*'s (1969a) investigation revealed imprecise consonants, pitch level, monopitch, mono-loudness, rate, and hypernasality to be prominent across the groups. Interestingly, consonants appeared more vulnerable than vowels. The results further showed that for a given neurological disease, not only did a single dimension turn out to be unique, also the cooccurrence of several dimensions was distinct. The five basic 'perceptual' patterns that thus were found were given physiological labels and termed flaccid, spastic, ataxic, hypokinetic, and hyperkinetic dysarthria. This labeling, reminiscent of that fashioned by the neurological perspective on dysarthria, found further elaboration and justification in Darley *et al.* (1969b, 1975). In Darley *et al.* (1969b), they mapped the cooccurrent

Table 1 Clusters of dysarthric speech dimensions and proposed associated neuromuscular deficits (Darley *et al.*, 1969b)

Cluster	*Deficit*
Articulatory inacccuracy	Inaccurate direction of movement
Prosodic excess	No direct physiological implication
Prosodic insufficiency	Restricted range of movement
Articulatory/resonatory incompetence	Impaired force of muscle contraction and reduced range of movement
Phonatory stenosis	Biased hypertonus
Phonatory/reonatory incompetence	Reduction in contraction force
Phonatory–prosodic insufficiency	Hypotonia

dimensions (clusters) on neuromuscular deficits. They are summarized in Table 1.

As can be seen there, Darley *et al.* (1969b, 1975) asserted a movement deficit as the basis for each cluster except for prosodic excess. Later, in their now classic monograph, Darley *et al.* (1975) went on to define the dysarthrias along with apraxia of speech within the concept of motor speech disorders. Unlike Peacher and Grewel, before, they drew a clear separation between apraxia of speech and dysarthria. Apraxia of speech in their view involved a deficit in one of three hierarchically organized conceptual motor stages (processes), including purpose formulation, movement planning, and programming that were separate, physiologically and anatomically, from the processes that involve movement execution (and control) and considered within the response province of dysarthria. The former processes were, except for the global cortical process of purpose formulation, considered left lateralized and had no direct neuromuscular implication or a prosodic consequence. Dysarthric processes, on the other hand, involved motor execution at the exclusion of sensory processes and were relegated to upper motor neurons (bilaterally), as well as extrapyramidal, cerebellar, and lower motor neurons.

The Mayo Classification has remained the gold standard in motor speech disorders for almost 40 years. Duffy's (1995) recent update of the theory added unilateral upper motor neuron dysarthria to the classification, but was otherwise faithful to Darley *et al.*'s founding principles. Like Darley *et al.*, he underscored the need for a strict adherence to a 'perceptual' roadmap guiding the classification of dysarthria and a pure motor interpretation of its neurophysiological underpinnings in accordance with a three-stage model of speech production, involving cognitive-linguistic, programming, and execution phases.

Within the last decade, Van der Merwe (1997) and Boutsen (Boutsen, 2003; Boutsen and Christman, 2002) have challenged some basic tenets of the Mayo classification. In line with research showing that the cerebellum and basal ganglia (BG) are involved with cognitive, linguistic, and motor aspects of speech, they argue that a sharp distinction between apraxia of speech and dysarthria is not tenable even in neurophysiological terms. In addition, underscoring the sensorimotor nature of speech, they assigned a pivotal role to audition and proprioception in speech disorders and argued that context specificity plays a role in motor speech disorders. Boutsen maintained in this regard that speech contexts variably tap into prosodic goals that are intrinsic or extrinsic to the language. His theory further argues that those strategies (processes) that serve goals across linguistic domains in a language-specific manner are predominantly elaborated by left hemisphere–right cerebellar circuitry, while those that serve to communicate pragmatic effect are lateralized in right hemisphere–left cerebellar circuitry. Accordingly, dysarthrias, if lateralized, may show differential impairment of these processes. In addition, in line with evidence that the role of the BG and the cerebellum changes fundamentally from childhood to adolescence, this theory predicts that the processes in adult dysarthria may not have much bearing on those observed in developmental dysarthria.

Speech Production

J Harrington and C Mooshammer, University of Kiel, Kiel, Germany

Introduction

The act of speech communication involves exchanging a complex set of codes between a speaker and a listener. These codes carry semantic information about the meaning of a spoken utterance in relation to an ongoing dialogue; social information about the speaker's dialect and possibly socioeconomic status; physical information about the speaker's gender, age, and size; and psychological information about the speaker's emotive state and mood. The 'production of speech' is concerned with how these codes are transmitted to the listener as movements of the vocal organs that give rise to an acoustic signal. In the 'perception of speech,' we are concerned with how the codes are recovered by the listener from a combination of the acoustic signal and the listener's knowledge of the language.

Studies of speech production are carried out in many different disciplines, including phonetics, linguistics, cognitive science, computer science, electronics, neurology, anatomy and physiology. Studies in many of these disciplines are concerned with both normal and disordered speech production. Data from slips of the tongue and other performance errors in normal speakers have been especially influential in developing our understanding of the different components that are involved in producing spoken language.

Because the study of speech production is so interdisciplinary, it is not surprising that it has relied on a wide range of types of experimental analyses and techniques. From a psycholinguistic and cognitive science perspective, speech production models are often developed using indirect analyses of speech production, such as measurements of reaction time to visual and/or auditorily presented stimuli. Phoneticians tend instead to be more concerned with direct measurements of the configuration and movements of the vocal organs and their relationship to the acoustic speech signal. These second types of analyses have been made possible by advances in the last 50 years of various instrumentation for quantifying the production of speech. Some of the most important of these include: aerometry for measuring air-pressure and airflow in the vocal tract; electrolaryngography for measuring vocal fold contact and vibration; direct fiber-optic laryngoscopy and transillumination, which can be used to measure the area between the vocal folds; palatography for measuring the extent of contact of the tongue against the palate; electromyographic techniques for recording the level of electrical activity in the muscles that innervate the vocal organs; X-ray microbeam and kinematic techniques for measuring the positions and movements of the tongue, lips, and jaw; and most recently, magnetic resonance imaging (MRI) techniques that have produced some of the sharpest images of the vocal organs ever seen. Analyses from all these experimental techniques are fundamental to 'articulatory synthesis,' which involves building a machine that can speak using an anatomical model of the vocal tract. The importance of articulatory synthesis and computer models of speech production is that they provide another source of evidence for verifying models of normal and disordered speech production.

There are good reasons for breaking down the task of speech production into a number of processes that operate largely independently of each other. It is common in much of the speech production literature to make a distinction between a conceptual or 'ideation' stage on the one hand, in which an idea to produce speech is formulated, and 'linguistic programming' on the other, in which the idea is represented in terms of linguistic categories. Within linguistic programming, a further distinction can be made between

'grammatical' and 'phonological' programming. The first of these is responsible for assembling a syntactic structure that is appropriate for the speaker's intended utterance, while phonological programming builds an abstract representation of the utterance's sound structure. Both grammatical and phonological programming must access a 'lexicon' containing a list of morphemes with links to their syntactic, semantic, and phonological information. Linguistic programming is often distinguished from the 'motor programming' stage of speech production that is responsible for producing a set of commands that result in coordinated movements of the vocal organs.

In the first section of this article, we begin by considering the interaction between grammatical programming, phonological programming, and the lexicon in terms of two influential models of speech production: the Weaver model developed by William Levelt and recent exemplar theories of speech production. Within that section, we will also consider the contribution of prosody to the linguistic and phonological stages of speech production.

As we will see at various points in this review, speech is inherently variable; an examination of both articulatory and acoustic records would show clear differences between two productions of the same words, even when produced by the same speaker under exactly the same conditions. Prosody causes one type of 'structure-dependent' or 'vertical' variability that comes about because of the way in which the same speech sound varies when it occur in different hierarchical positions of the syllable or in different positions of larger phrases. Another type of 'horizontal' variability that is discussed in the section on coarticulation is due to the sequential arrangement of speech sounds.

In the final section, 'motor programming,' we will have to consider how the brain manages to control the hundred or so muscles that are activated per second in producing speech. Of importance here – in light of what is known about immediate compensation, i.e., the ability to achieve the same speech goal even when some of the vocal organs are artificially prevented from doing so – is how the muscles are coordinated to achieve different speech tasks. This analysis will consider the importance of feedback and 'feedforward' in stabilizing the speech production system. Another area to be considered here is the space in which speech production is planned – whether this is in the form of articulatory or auditory targets, for example.

There are a number of areas of investigation in speech production that we will not be able to consider here. Firstly, we will not include much discussion about the neurological aspects of speech – that is, the extent to which cognitive processes of speech production can be linked to specific areas of activity in the brain. Secondly, detailed discussion of disorders of speech are beyond the scope of this article. Thirdly, we will not be able to discuss those aspects of speech production that communicate mostly personal (social, physical, psychological) information referred to earlier. Finally, while nonvocal aspects of speech communication such as head-movements, body movements, facial expression, eye contact, and body movements all contribute to the sets of meanings that are exchanged in speech communication, a detailed consideration of these is also beyond the scope of this article.

The Grammar, the Lexicon, and Prosody

The Weaver Model

The most complete model of speech production – in the sense that it attempts to cover all the stages of speech production (beginning with the formulation of an idea to speak through to the movement of the vocal organs) – is the Weaver model developed by William Levelt over a number of years. As Levelt *et al.* (1999) note, the arguments for many aspects of the model are based mostly on latency data, i.e., on indirect measurements of speech production from various kinds of naming experiments. 'Weaver' stands for 'Word-form Encoding by Activation and VERification'; a schematic outline of the model is shown in Figure 1. Weaver is a top-down model in that information flows from more to less abstract levels of speech production.

The Weaver model adopts the idea from earlier research of slips of the tongue that there is a sharp distinction between grammatical and phonological programming and that the mental lexicon is accessed first for grammatical information to fill an emerging syntactic structure and then again separately for phonological information to fill the emerging phonological structure. There is a similar division in the lexicon in which the information about the word's syntactic properties, known as its 'lemma,' is stored separately from its 'word-form,' which includes specifications about its morphology and phonology.

A lemma is activated by a set of semantic concepts. For example, a picture of a ball might activate a number of semantic concepts such as 'round,' 'used in games,' 'inanimate,' and so on, and each activated lexical concept activates the lemma to which it is attached. A number of candidate lemmas are therefore initially active, and whichever one receives the highest level of activation is the one that is selected to be inserted into an emerging syntactic frame.

Figure 1 The Weaver model of speech production. Adapted from Levelt *et al.*, 1999.

The selected lemma then activates the corresponding word form that includes information about its phonemic composition, a representation of the number of syllables, information about which syllable has primary word stress, and information about its morphological composition, including, for example, a division into a stem and any number of affixes. Only one word form per lemma is activated, the only exception to this being if the semantic concept has two synonyms (such as 'couch' and 'sofa'). Word-frequency is built into the system only to the extent that the access is slower for words of low frequency (those that tend to be less frequently used) than those of high frequency.

For each selected lemma of the utterance, a morphological frame is built into which the phonological information is slotted. The morphological frame is essentially a placeholder for each morpheme. For example, 'unkind' has two morphological placeholders: the affix ('un') and the stem ('kind').

Syllabification comes about when the phonological information stored in the lexicon – that is, the number of syllables, a word-stress pattern if the stress-pattern is irregular, and the lemmas' phonemes – are associated with the morpheme placeholders. Syllabification follows the maximum onset principle, in which as many consonants as possible are syllabified with a following vowel, provided that the resulting sequence can legally begin words. If more than one word-form has been retrieved, syllabification can cross word boundaries – and therefore word-final consonants can be syllabified with a following word-initial vowel in this model (so the /t/ in 'get us' is syllabified with 'us').

The output of the phonological program is, therefore, a string of phonemes structured hierarchically into syllables and morphemes. There is then a 'phonetic implementation' of this program in which articulatory routines for syllables that are stored in a syllable lexicon or 'syllabary' are accessed. The syllabary is assumed to contain articulatory routines only for the most frequently produced syllables (and so procedures are needed to compute those that occur infrequently). There are also mechanisms for further modifying the loudness, pitch, and duration parameters of stored articulatory syllables to take into account some of the effects of sentence prosody (see the section 'Utterance-Level Prosody' in this article). Various proposals have been made for the need to include a mechanism for monitoring speech production internally – this is an evaluation of the intended speech utterance before the vocal organs move creating auditory feedback. Based on various experiments, this would correspond to internal monitoring mechanism operates when a lemma's phonological form in the lexicon is activated.

Exemplar Theory

Weaver and many other speech production models based on performance errors adopt the idea from generative phonology that there is a phonological grammar and a component for phonetic implementation that is independent of the words in the lexicon. The grammar contains a set of rules that will apply to words in the lexicon irrespective of any word-specific properties such as the frequency with which they occur.

Recently, exemplar theory and usage-based based phonology (Bybee, 2001; Pierrehumbert, 2003) have challenged the idea that there is a phonological grammar with rules applying across the board to lexical items. The proponents of other models also argue against the idea that the lexicon only contains nonpredictable, phonological information

for distinguishing words' meanings in terms of their sounds.

In exemplar and usage-based phonology, a good deal of phonetic information – that is, phonetic detail below the level of the phoneme – is stored as part of the word's lexical representation. In contrast to generative phonology, a word is not a minimal, context-free abstract arrangement of symbols. Instead, it is a storage unit or multidimensional probability distribution for the set of exemplars of that word that have been experienced by the speaker/hearer. The exemplars are trajectories in a multidimensional auditory space (Johnson, 1997), and phonemes emerge from points in this space at which the words' exemplars give rise to dense regions of intersection. Since the relationship between a word and its exemplars is probabilistic, frequency information is represented in the lexicon in two different ways. First, as in the perceptual magnet theory (Iverson and Kuhl, 1995), exemplars at the center of the distribution are more representative of the particular word as spoken in the community than are exemplars at the edge of the distribution. Second, information about the frequency with which words occur is an emergent aspect of this model, because low-frequency words, being heard and produced less often, will be associated with fewer exemplars and hence characterized by less stable and more malleable probability distributions.

As far as phonotactics are concerned, in generative phonology these tend to be all-or-none; a sequence of phonemes can either begin words (e.g., /spr/, as in 'spring') or it cannot (e.g., /sfr/ is illegal in English because there aren't any words that begin with this sequence of phonemes). This type of all-or-none phonotactic principle is also at the heart of the syllabification of the Weaver model considered earlier: the syllabification has to work out whether a string of consonants is phonotactically legal and then place a syllable boundary accordingly. In exemplar theory, by contrast, the legality of a sequence of phonemes is not binary but gradient and depends on the likelihood with which a sequence is found in the lexicon. Accordingly, speakers don't make categorical judgments about the well-formedness of a syllable (see Beckman and Edwards, 2000 for supporting evidence from child language acquisition), and proponents of exemplar theory consider it implausible that speakers categorically divide up phonemes into syllables based on the maximum onset principle as in the Weaver model.

A word in exemplar theory may well be represented as an abstract label in the lexicon, but this label is associated probabilistically with all the tokens or exemplars of that word that have ever been heard during a speaker's lifetime. In speech production (Pierrehumbert, 2003), the exemplar to be produced is selected from a random sampling of the exemplars for that word label, and because the association between a word and its exemplars is probabilistic, the exemplar selected is most likely to be nearer the center (i.e., the most probable exemplar) of the distribution. The production goal is then assumed to be 'executed with noise.'

It is clear that the notion of a syllable of stored articulatory routines in Weaver is at odds with exemplar theory for at least two reasons: first, the idea of an articulatory routine being stored seems to preclude the possibility that it can vary probabilistically, and second, because the articulatory characteristics of the syllable would vary in exemplar theory across words of different frequency, even if they are of the same phonological structure.

Utterance-Level Prosody

We consider here briefly some aspects of utterance-level prosody partly because these are not integral parts of the current Weaver or exemplar models of speech production reviewed above and partly because these have important implications for modeling variability considered in the next section.

Changes to an utterance's timing, pitch, and loudness can be used to communicate emotions like anger, happiness, and surprise. These modifications can also be used linguistically to distinguish between words (word-level prosody) or to add new meanings to utterances (utterance-level prosody). Prosodic effects usually extend over, and modify, more than a single consonant or vowel; this is why the units of prosody are sometimes called 'suprasegmentals.' Word-level prosody includes at least how words are represented in terms of their syllable structure and stress pattern, and these types of representations are included in the Weaver model reviewed earlier. Utterance-level prosody includes 'intonation' and sentence-stress or 'accentuation.' Intonation can change the meaning of an utterance by turning a statement into a question in many languages. But intonation can also change meanings without affecting the syntax, which suggests that they must be independent of each other in a speech production model. For example, in producing the following sentence:

I don't collaborate with anyone

The pitch usually falls on 'anyone' in many accents of English to convey the meaning 'I work alone.' Now consider a context like:

A: Have you thought of working with Peter?
B: I don't collaborate with anyone

If 'anyone' is produced with a falling-rising pitch, the meaning is very different, one of selection: although B is still willing to collaborate with someone, it certainly wouldn't be with someone like Peter whom he regards with some disdain. A model of speech production must therefore include a component containing a number of different intonational melodies or 'tunes' that are associated with words, or the 'text,' of the utterance. The domain over which this association is made is often known as a 'prosodic phrase.' The shortest prosodic phrase is a single-word monosyllabic answer like 'yes' or 'no,' and it can extend across several words, as the examples above show.

The choice of prosodic phrasing can also be independent of syntax. It's quite possible to produce A's question as two prosodic phrases (and hence two intonational melodies) with a prosodic phrase boundary after 'of' that might be used in a context like 'have you thought of working with' – (gasp of incredulity) – 'Peter?' to indicate that this would indeed be a surprising thing to consider doing. But prosodic phrasing clearly can reflect syntactic cohesion. This is shown by the title of a recent book by Lynne Truss, *Eats, shoots and leaves*. When this is said as one prosodic phrase (analogously in orthography, without commas), the meaning might be that (a panda) eats both shoots and leaves, but to communicate the other syntactic form of eating, shooting someone or something, and leaving, the same utterance would be likely to be said as three prosodic phrases.

Accentuation specifies how prominent words are in a prosodic phrase. This specification is closely linked with intonation, but nevertheless independent of it, as the earlier example with 'anyone' shows: although 'I don't collaborate with anyone' can be produced with two different intonational melodies, the two most prominent or accented words of the utterance are the same ('collaborate' and 'anyone' in both cases). Accentuation can also be varied independently of syntax to contribute its own layer of meaning. Consider saying the sentence 'I don't like classical music' on its own. Usually this would be done with all words except 'don't' being accented to the same degree. On the other hand, in a dialogue like:

A: Have you listened to Beethoven recently?
B: I don't like classical music.

the most prominent word is 'like,' and both 'classical' and 'music' are said without any prominence and are deaccented. They are deaccented because as long as B realizes that Beethoven was a composer of music, then 'classical music' is part of the shared, understood information evolving in the discourse and so is put into the background in spoken communication using this device. Because the same sequence of words in the same prosodic phrase can be produced with these different accentuation patterns, accentuation must also operate independently of syntax in a model of speech production.

Variability

Speech is inherently variable. The same utterance, word, and sounds can be said even by the same speaker in a multitude of different ways. Variability can be considered to be a necessary aspect for communicating multiple layers of meaning effectively. The multiple layers of meaning are derived not only from words standing in a certain syntactic relationship to each other, but also because intonation, accentuation, and prosodic phrasing all contribute their own levels of meaning to the utterance and to the relationship of the utterance's meanings to those established in an ongoing dialogue. The skilled listener decodes effortlessly all the meanings that are communicated in parallel, but at the same time, there is a limiting effect imposed on the speaker in that much of speech production is necessarily serial: words, after all, have to be said in a certain sequence one after another, and although speech sounds can and do overlap with each other in time, there is a necessary serial order here as well (so that 'cat' remains distinguishable from 'tack'). The way in which communicating meanings in parallel can be reconciled with the limiting effect of serial order in speech production is to make speech sounds highly 'context-sensitive' – that is, dependent on the context in which they occur. We consider in the following sections some of the main sources that contribute to context-sensitivity at different levels.

Hyperarticulation and Hypoarticulation

The theory of hyperarticulation and hypoarticulation (or H&H theory), developed by Björn Lindblom over a number of years (Lindblom, 1990), models variability as a tension between the speaker's natural tendency to economize on speech effort and the listener's need for speech to be produced clearly. The first of these, also known as 'hypoarticulation,' is evident in the production of forms like 'hambag' for 'handbag.' This is a form of hypoarticulation, because the more complicated /ndb/ sequence is simplified to /mb/, where the nasal and following stop share the same place of articulation. Hypoarticulation tends to occur to the extent that meaning is not compromised for the listener; thus, 'handbag' can be reduced in this way precisely because it is very unlikely that the sequence of sounds corresponding to 'hambag' could be anything other than the object designated

by 'handbag.' Similarly, 'fast speech' can be said without the final /t/ on 'fast' because even with this impoverished information, the listener can easily recover 'fast' from 'fas' in such a context. 'Hyperarticulation' comes about when speech is produced with a greater than usual amount of distinctiveness or clarity. When a person's name is said for the first time, this would almost certainly be hyperarticulated, especially if the person is not known to the listener. Here, the listener has no contextual cues of any kind that would make the name more predictable, and so the speaker has to make sure that all the information for decoding the name is contained in the acoustic signal. According to Lindblom, speech varies continually between the speaker's desire to *hypo*articulate and the need at the same time to *hyper*articulate so that the meaning of the utterance is not compromised. H&H theory has also been used to explain why certain types and patterns of sounds occur in many different languages with regularity, and it is also very relevant for explaining some of the mechanisms of historical sound change.

Variation between hypoarticulation and hyperarticulation doesn't just depend on the listener's ability to predict; it also depends on factors such as the formality of the speaking situation. For example, Hawkins (2003) gives various examples of the production of 'I don't know,' noting that 'dunno' is preferred either in informal situations or to convey a certain degree of insolence in more formal ones. These words could even be reduced to little more than three weak, nasalized vowels heavily overlaid with sentence-prosody; in the appropriate situational and social context, listeners nevertheless manage to recover the meaning 'I don't know.'

Variation and Prosody

A large degree of variability due to hypoarticulation and hyperarticulation is played out through the utterance's prosodic structure. For example, because in Germanic languages accented words usually communicate points that are especially important to the listener for understanding what is being said – that is, they tend to be 'points of information focus' – they are usually hyperarticulated and produced with the greatest degree of clarity. On the other hand, because function words and grammatical words like 'it,' 'he,' 'should,' and 'and' are usually entirely predictable from the context, they are almost always unaccented and hypoarticulated. In German, 'mit dem Auto' ('with the car') is hardly ever produced as four distinct syllables; it is much more commonly produced as 'mim Auto' or even 'm Auto.'

As far as lexical stress is concerned, an unstressed syllable tends to be hypoarticulated, leading again to a reduction or deletion of any, or all, of its constituent speech sounds. In the spontaneously produced 'government support,' the last two syllables of 'government' might be produced as just a long nasal consonant, while 'support' might become more or less homophonous with 'sport.'

Prosody imprints many other types of context-sensitive signatures on the production of speech. The last syllable in a prosodic phrase is typically lengthened in many languages, including English, and there is now increasing evidence from various speech production studies that consonants are strengthened at the beginning of prosodic phrases. Consonant strengthening is manifested as the tendency for stricture – that is, the extent to which the vocal tract is obstructed – to increase. Thus, when 'tap' occurs at the start of the prosodic phrase, there is greater contact of the tip of the tongue against the roof of the mouth than when it doesn't. There's also some evidence that this effect is manifested lower down the prosodic hierarchy, so that there is slightly greater contact for the /t/ of 'tap' where it begins a word than in a word like 'attack,' where it doesn't. Information about the position in a prosodic phrase is also communicated in some languages by the way in which an intonational melody is synchronized with the text or words of the phrase. An intonational melody is in most frameworks considered to be made up of a number of smaller phonological units known as 'pitch-accents' that cause local pitch peaks and pitch troughs that can be seen acoustically in a display of the fundamental frequency contour. In many languages, pitch-accents that occur early in a prosodic phrase tend to have fundamental frequency maxima that are synchronized late in the syllable and vice-versa.

The position of a speech sound also varies depending on its position in the syllable. In many languages, consonants at the beginning of syllables are produced more distinctively and are overlapped or coarticulated (see the next section) less with a following vowel than those at the end of the syllable. But there are also many manifestations of syllable-position that are not explicable in terms of such strengthening effects, and these can be specific to languages and dialects. For instance, in many accents of English, there are two very different kinds of /l/: at the beginning of syllables (as in 'leaf'), /l/ is produced with a contact of the tongue tip against the alveolar ridge; in final position, this contact tends to be much weaker and overlaid with a raising of the back of the tongue known as 'velarization.'

Coarticulation

The type of phonetic variability discussed above is largely 'structure-dependent' in that it comes about because of the organization of a sound into larger units like syllables, words, and prosodic phrases. Thus, the velarization of /l/ is brought about by the structural position of /l/ in the syllable and not by the arrangement of sounds in sequence or by 'coarticulation.' Coarticulation, or coproduction, means that speech sounds in sequence are produced in at least a partially overlapping manner. For example, producing the last two sounds of 'pan' involves, among other things, changing from an oral vowel /a/, in which the velum is raised, to a following nasal consonant /n/, in which the velum is lowered. But because the velum can't move instantaneously from raised to open, it already starts to lower during the /a/, making the vowel nasalized well before the tongue tip touches the alveolar ridge for /n/. The production of /a/ is therefore influenced by, or said to be coarticulated with, the following /n/; it is because of coarticulation that the /a/ in 'pan' is phonetically very different from the /a/ in other contexts such as 'pad.' Coarticulation is ubiquitous, and because speech sounds can be communicated at a faster rate if they overlap with each other in time, some theorists, including proponents of the motor theory of speech perception, have argued that coarticulation is necessary to ensure that speech is produced sufficiently rapidly.

'Anticipatory coarticulation' comes about when a sound is modified due to the influence of another that follows (as when /a/ is influenced by /n/ in 'pan'). An example of anticipatory coarticulation using lip-aperture data obtained from an electromagnetometer system is shown in Figure 2. These lip-aperture data show two averaged trajectories in a sequences /məbi/ (solid) and /məba/ (dotted). In

Figure 2 Lip-aperture (as estimated by subtracting the vertical heights of transducers attached to the upper and lower lip respectively) in a sequence /məbi/ (solid) and /məba/ (dotted) produced by a female speaker of (Australian) English. Higher positions on the vertical axis represent greater lip-aperture (greater distance between the transducers attached to the upper and lower lips).

producing /i/, the lips are a good deal closer together than in /a/, and as Figure 2 shows, this influence extends anticipatorily across the preceding /əb/ sequence. In 'perseverative coarticulation,' the influence derives from a preceding sound: in English, /t/ in 'boots' tends to be produced with rounded lips due to the influence of the preceding lip-rounded /u:/ vowel.

In many models (discussed in further detail later in this article), anticipatory and perseverative coarticulation are thought to arise at different stages in speech production. Anticipatory coarticulation is often assumed to be more closely associated with the planning stage of speech production, whereas perseverative coarticulation is instead attributed to the inertia and sluggishness in moving the vocal organs within a sufficiently short time. However, there is now evidence to show that that perseverative coarticulation is also largely planned, but to a much lesser degree than anticipatory coarticulation.

Context-Variant Theories of Coarticulation in the 1960s and 1970s Although a word like 'won' can be represented as three separate phoneme size units, there is nothing in the speech signal to suggest that their unambiguous separation is analogous to the separation between letters on a printed page. Similarly, although printed words are clearly demarcated from each other by at least one intervening blank space, vocal performance is continuous across word boundaries, and there is often nothing in either articulatory or acoustic records of speech that demarcates where one word ends and the next begins. Since the late 1960s, theories of coarticulation have been concerned with this wider problem of the rift between invariant nonoverlapping phonemes on the one hand and the continuum of vocal performance on the other. In context-variant theories of coarticulation, the assumption is that speech is planned in terms of units like phonemes that are free of the influences of context, but that these context-free units are then modified by adding phonetic detail. Thus, 'soon' and 'see' are assumed to be represented at some abstract stage of speech production with the same context-free unit /s/ that would be modified by the rules of coarticulation, resulting in a lip-rounded production of /s/ in 'soon' (due to the influence of the following rounded vowel) but not in 'seen.'

One of the earliest and best known context-variant theories is that of Henke (1966), who developed a two-dimensional computer model of the vocal tract controlled by an independent time function. The input to the model is a string of phonemes; each phoneme is described by an invariant articulatory representation.

Rules of anticipatory coarticulation are expressed as a 'look-ahead mechanism' that scans one phoneme ahead to make corresponding adjustments to the articulatory representation of the current phoneme. Specifically, the feature-matrix defining the /s/ of 'soon' would be modified to include the feature [+round] (produced with rounded lips). In subsequent coarticulation models incorporating a look-ahead mechanism (e.g., Daniloff and Hammarberg, 1973), anticipatory coarticulation is also thought to apply in this look-ahead way, but only as long as the anticipated feature doesn't contradict any of the features of a phoneme to which the anticipated feature is attached. So while the [+round] feature could attach itself to the first three consonants in 'stroop,' it could not attach itself to the [i:] vowel of 'pea' in 'pea-soup' because [i:] is inherently specified as being [−round]; i.e., to be produced with spread lips – and sounds obviously can't be simultaneously produced with a rounded and spread-lip configuration.

Numerous studies in the 1960s and 1970s were concerned with establishing the extent of look-ahead and the related issue of what factors caused coarticulation to be blocked or diminished. An earlier and influential model by Kozhevnikov and Chistovich (1965) had provided evidence that speech – and by inference coarticulatory spreading – is produced in sizes of articulatory syllables, where an articulatory syllable includes one or more consonants and a following vowel irrespective of any intervening syllable or word-boundaries. However, this model was shown to be incompatible with an influential study by Öhman (1966). He provided evidence for 'trans-consonantal vowel coarticulation': V_2 can and does influence V_1 (i.e., across syllable-boundaries, assuming the vowels are in separate syllables) and vice-versa in a V_1CV_2 sequence.

Other studies showed that the domain of look-ahead coarticulation could not be defined in terms of anything as simple as whether features were contradictory. For example, Benguerel and Cowan (1974) showed that unrounded vowels are nevertheless slightly rounded when they precede rounded vowels. Other studies showed that coarticulation is more complicated than filling in details provided by anticipatorily copied features. Consider a sequence like /ipi/ in which /i/ must be specified for tongue body raising while /p/ is unspecified for any lingual activity (because it is a labial consonant). According to an anticipatory feature-copying account of coarticulation, the tongue body raising feature should spread to the medial labial consonant /p/. In fact, electromyographic studies suggest that the degree of tongue body raising is not maintained to the same degree across these high vowels – that is, during the production of the /p/ consonant, the tongue body is lowered, even though there is nothing in the feature matrix, nor in its modification after copying the tongue-body features from /i/, to explain why this should happen (Engstrand, 1983).

A more general problem with feature-spreading accounts of this kind is that the output doesn't get us very much closer to vocal performance. As some have argued (e.g., Fowler, 1990; Pierrehumbert, 1990), this is largely because coarticulation is being explained using devices that belong to phonology and that are not appropriate for phonetic modeling. Phonology, like syntax, deals with operations on discrete sets of categories that can to a large extent be expressed in terms of rewrite rules that take a set of symbols as an input and derive some form of symbolic output. Phonetics on the other hand, has to model physical events, such as how vocal tract movements are related to an acoustic speech signal. Because we can't have a rule that converts a symbol into something physical, it is never clear how a speech plan made up of symbols – even ones with lots of phonetic detail – could ever actually get the vocal organs to move.

Context-Invariant Theories of Coarticulation The objection raised in the previous paragraph is one of the factors that led Fowler to propose a context-invariant theory of coarticulation. In context-invariant models, there are two core principles: first, a phoneme is a physical, dynamically changing event of vocal tract movement, and second, phonemes are invariant, which means that the aspects of their articulatory properties remain the same in all contexts – in spite of the effects of coarticulation and prosody-dependent variation described earlier. It is because of this second principle that phonemes can be 'directly perceived' by the listener.

These ideas are most explicitly formulated in Fowler's action theory and direct realist model of speech perception, which is inspired partly by Gibson's (1966) theory of direct perception. It is also based on studies by Öhman (1966) in which it is hypothesized that consonants and vowels are produced by largely independent subsets of the vocal tract musculature. In Fowler's (1984) model, consonants and vowel phonemes are defined by independent articulatory gestures known as 'coordinative structures' that overlap with each other in time. In earlier versions of this model, coarticulation was assumed to come about not because phonemes are modified in any sense but because of the temporal overlap of completely autonomous coordinate structures, one for each phoneme. Thus, in the production of 'see,' the coordinative structures for /s/ and /i:/ are not modified but coproduced (produced simultaneously). At faster

rates of speech, the extent of overlap is increased, and accordingly, more of the vowel is covered up by the consonant and vice-versa. Because phonemes increasingly cover each other up at faster rates of speech, they **appear** to shorten. Thus, although a faster production of 'see' is likely to be several tens of milliseconds shorter than a slow production, the shortening doesn't come about through changing the articulatory strategies that underlie /s/ and /i:/. This is because these articulatory strategies are assumed to be invariant (the second principle), and the shortening is entirely attributable to their greater overlap in time. The same argument applies to compensatory shortening in which vowels **appear** to shorten when measured acoustically before consonant clusters (e.g., 'sixths') than before singleton consonants (e.g., 'six'). The acoustic shortening is only an illusion that comes about because the articulatory strategies cover each other up at faster rates.

The strong version of this theory predicts that segments are never deleted (i.e., a phoneme is always physically instantiated). So even at very fast rates of production, 'support' always remains distinct from 'sport,' and if they seem to be homophonous even to skilled experimental phoneticians, this is only because they are not measuring the differences in the right way.

A model like Fowler's, in which articulatory duration is invariant, makes a very different prediction about the extent of anticipatory coarticulation than does the feature-spreading model considered earlier. If the articulatory duration is fixed, the time at which lip-rounding begins should be fixed or time-locked relative to some other event in the vowel. Some evidence in favor of the time-locked model is provided in Bell-Berti and Harris (1981). Subsequent experiments, including Perkell and Chiang (1986), have suggested instead a compromise between a feature-spreading and a time-locked model.

Fowler's direct realist view of speech perception takes over the idea that speech is perceived with reference to how it is produced from the motor theory of speech perception. A central difference, however, is that the motor theory holds that speech is perceived with reference to the listener's own motor (articulatory) system, while in Fowler's direct realist model, consonants and vowels are **directly** perceived in the acoustic signal. This is done essentially by factoring the acoustic signal into the separate coordinative structures that were produced by the speaker. Consider, for example, the production of /ki:/ ('key') in which the body of the tongue for /k/ is considerably fronter than before a back vowel in /ku:/ ('coo'). In both cases, the listener decodes the same coordinative structure for /k/ by subtracting out the vowel coordinative structure. This subtraction of independently produced coordinative structures is analogous to perceiving a child on a horse that moves up and down on a merry-go-round. The two types of motion (vertical and circular) fuse to cause the child to move along a complex cycloid path, but this is not what viewers perceive; a viewer instead perceives both the vertical and the circular movement **independently of each other** (analogously, consonants and vowels are independently perceived because they are independently produced events).

Many of the ideas of Fowler's coproduction model are incorporated into the 'task-dynamic theory of speech production' developed by Saltzman and Munhall (1989), which provides a computationally explicit model of coarticulation. In this model, a phoneme is made up of one or more abstract 'tract variables' that define the extent of constrictions along the longitudinal axis of the vocal tract. A tract variable for /p/ is specified as lip-closure that in turn is achieved by the coordinated activity of a number of independently controlled articulators that cooperate to achieve this task. The coarticulatory influence of speech sounds in sequence depends on the extent to which the overlapping gestures share articulators. For example, in a /VbV/ sequence, the vowels and intervening labial consonant are produced using largely different sets of articulators (the tongue body for the vowels; the lips for /b/). For this reason, they perturb each other minimally when they overlap with each other in time. On the other hand, there is considerably more spatial perturbation between the vowels and the consonant in a /VgV/ sequence because /g/ and the vowels compete for the same articulator (the tongue dorsum).

The competition between segments that share largely the same articulators is resolved in Saltzman and Munhall's (1989) task-dynamic model by a 'blending' of the segments that depends on the 'articulatory strength' of the two segments being merged or blended (Fowler and Saltzman, 1993). In some cases, blending might consist of a form of averaging. For example, the blending of an alveolar /t/ and a dental /θ/ might be resolved as a place of articulation that is somewhere between alveolar and dental. Articulatory strength defines how resistant a segment is to coarticulatory influences; in general, the more resistant a segment, the greater its influence on neighboring segments (i.e., coarticulatory resistance and dominance are roughly inversely proportional). So the outcome of blending is always in favor of the segment that is articulatorily stronger.

The idea of articulatory strength can be traced back at least to Bladon and Al-Bamerni's (1976) model of 'coarticulatory resistance,' in which segments are

weighted for the extent to which they resist coarticulation. In the last 20 years, Recasens has carried out various electropalatographic and kinematic investigations of the relationship between coarticulatory resistance and dominance, which he expresses in terms of a 'degree of articulatory constraint' (DAC) value (see e.g., Recasens, 1999). For example, palatal consonants are generally associated with a high DAC value, presumably because the tongue body movement is very constrained when the tongue dorsum is in a raised and front position (as for palatals). Accordingly, palatals tend to block vowel-to-vowel coarticulation in VCV sequences or at least far more than do alveolars in which the tongue dorsum can still adopt the configuration for the vowels while the tongue tip is raised to the alveolar ridge for the production of the consonant.

The Window Model of Coarticulation The idea that segments are inherently resistant to coarticulation is central to Keating's (1990) window model of coarticulation, but here there is a greater emphasis on phonetic aspects of coarticulation and their relationship to phonology. The width of the window in this model is essentially a summary of the range of permissible variation of the features that make up abstract, subphonemic units or extrinsic allophones (these are units that include language or dialect-specific phonetic detail). Keating's model also adopts the idea of coarticulation resistance from Bladon and Al-Bamerni (1976), that subphonemic units are differently specified for the extent to which they resist coarticulation. But an importance difference is that for Keating the range of allowable variation is at the feature level. In the case of /s/, for example, there will be a window specifying the range of allowable variation in tongue constriction at the alveolar ridge, another one specifying the range of variation in lip-rounding for /s/, and so on. All these window widths are fixed; that is, they don't vary when /s/ occurs in different contexts. Window widths are not universal; they vary idiosyncratically between languages and dialects, and they depend partly on whether a feature is phonemic, i.e., used for meaning distinctions in a language. Thus, in English the window width specifying velum height in vowels is large, partly because the oral–nasal distinction isn't phonemic in English. Because, on the other hand, the oral–nasal distinction **is** phonemic in French vowels, the corresponding window must be narrow to avoid confusions between e.g., /vɛ/ 'vais' meaning 'go') and /vɛ̃/ ('vingt,' meaning 'twenty'). At the same time, Keating emphasizes that window widths don't just depend on phonemic contrasts but may be idiosyncratic to languages or dialects. Thus, although both Russian and Japanese have a basic five-vowel phonemic contrast, the range of phonetic vowel variation is much greater in Russian; this would be modeled by specifying features of Russian vowels for wider windows than those of Japanese.

The extent of coarticulatory overlap between segments depends on how close a 'trajectory' passes to the edge of a window. This is illustrated in Figure 3, which shows a hypothetical trajectory of velum height through three windows, one each for the three segments in 'man.' For /m/ and /n/, the window is narrowly specified for a lowered velum position (the windows are narrow for these segments to avoid confusion with /b/ and /d/, respectively). Production of velum height for this word is defined by the trajectory that follows more or less the shortest possible path through the windows. Being flanked by two nasal consonants with a narrowly specified window for a lowered velum, the trajectory necessarily passes around the edge of the window for /a/, which represents the maximum amount of allowable velum opening for this vowel, and as a result, /a/ is heavily nasalized. But the extent of nasalization in /a/ isn't as extreme as for /m/ or /n/, because the window width for /a/ specifies that the maximum allowable nasalization is less than that of nasal consonants. In terms of this model, the diminution of lip-rounding in /s/ of /usu/ or of tongue-body raising in /p/ of /ipi/ considered earlier (see the section 'Context-Invariant Theories of Coarticulation' earlier in this article) would come about because their windows are less than the maximum possible extent of lip-rounding or tongue-body raising, respectively.

The window model is one of the first to provide a systematic account of 'underspecification.' In much of phonology, a segment is assumed to be unspecified for a feature if it is not used for meaning distinctions. Thus, English vowels are lexically unspecified for nasality, which means that it doesn't matter as far as meaning distinctions are concerned whether the velum is raised or not during their production. In some of the context-variant theories reviewed earlier, anticipatory coarticulation essentially involves

Figure 3 Keating's window model. The horizontal line represents the edges of the windows within which variation of velum height (vertical dimension) can occur for the three segments /mæn/ ('man'). The dotted line shows the hypothetical trajectory that is calculated for velum height in producing these three segments.

copying features into unspecified slots. So in a production of 'ban,' the nasal feature that is specified for /n/ is copied into the unspecified oral/nasal slot for /a/, an action that turns /a/ into a nasal vowel. One of the problems with this account was alluded to at the end of the section 'Context-Variant Theories of Coarticulation in the 1960s and 1970s,' earlier in this article: coarticulation is being modeled in terms of symbols, procedures, and a grammar that belong to phonology, whereas this type of change is at least partly a consequence of the physical and temporal properties of speech production that are best modeled in terms of windows specifying a permissible range of variation.

Coarticulation that arises at the level of trajectories through windows is distinguished sharply in Keating's (1990) model from phonological rules that change features; one of the distinguishing properties is that phonological rules tend to be all-or-none or 'categorical.' Consider, for example, a language like Japanese, whose consonant clusters in the lexicon are obligatorily homorganic – that is, there are words like 'tempura' and 'bento' with /mp/ and /nt/ clusters that have the same place of articulation, but there are no Japanese words built from consonant sequences like /mt/ with different or heterorganic places of articulation. What happens, then, when Japanese speakers are asked to produce a blend from two words that could potentially result in a heterorganic sequence? The answer is that they generally make it homorganic, and categorically so (Stephenson and Harrington, 2002). In a blending experiment, Japanese listeners hear hypothetical town names like 'Rundo' and 'Makapa' and are asked to say a new name consisting of a combination of the first syllable from the first word followed by all noninitial syllables from the second word (thus, 'run+kapa,' in this example) as quickly as possible. But rather than producing the blend as /runkapa/ with a heterorganic /nk/ they instead produce /ruŋkapa/ in which the consonants in the /ŋk/ sequence have the same velar place of articulation. This change from what must have been /nk/ at some abstract level in the production system in which the two separate words are specified to homorganic /ŋk/, is mostly categorical. That is, there isn't a wide range of variation between the alveolar /n/ and the velar /ŋ/ – speakers on the whole just produce /ruŋkapa/ and not something between this and /runkapa/.

Compare this study of Japanese with a number of recent articulatory experiments designed to investigate assimilation of place of articulation in English (e.g., Holst and Nolan, 1995). The analysis of utterances like 'ten cars' shows that some of the time there is complete assimilation in which the consonants across the word boundary are homorganic as in /tɛŋkɑz/; sometimes there is no assimilation resulting in heterorganic /tɛnkɑz/; but sometimes speakers produce an /n/ which is between the two, i.e., with simultaneous alveolar and velar closures. This is a very different outcome from the experiment in Japanese, and one of the ways of expressing these language-dependent differences is to say that whereas assimilation is phonological and categorical in Japanese, in English it is phonetic and involves constructing one of a number of possible paths through a fairly wide place of articulation window for /d/ in word or syllable-final position.

Coarticulation, H&H, and Locus Equations Most investigations of coarticulation have shown that there is a good deal of variability in the extent of coarticulation: there are differences in the magnitude and direction of coarticulation between speakers, possibly even between age groups and (as the preceding section showed), between languages and perhaps even their dialects. There is also considerable variation in coarticulation across speaking style. This, according to the H&H theory discussed in the section 'Hyperarticulation and Hypoarticulation' earlier in this article, is to be expected. The goal of speaking is not to achieve articulatory or acoustic invariance, but is instead to communicate meanings to the listener within a certain social and situational context. In general, greater coarticulation is a form of hypoarticulation that is likely to be more prevalent either when the meaning is not compromised (because it is predictable from context) and/or in more relaxed speaking situations. The findings that coarticulation itself should show considerable variation is, then, entirely consistent with H&H theory.

In recent years, some of these relationships between speaking style, variability, and coarticulation have been quantified using data from second formant frequency transitions in consonant–vowel sequences. In general, an F2 transition is influenced both by the place of articulation of the consonant and the phonetic quality of the vowel. In producing /bi:/ ('bee') for example, there is an extensive F2-transition from a low value for labial consonants to a high value for high vowels. The outcome of increasing the extent of coarticulation between these sounds is a diminished transition. This is because if /b/ is influenced by /i:/, then its F2-starting point shifts towards the high value associated with /i:/; and if /i:/ is influenced by /b/ (this is sometimes called 'vowel undershoot'), then the high F2 value for /i:/ shifts towards the lower value associated with the preceding /b/. Various experiments have shown exactly this type of diminution in the extent of the F2-transition with a less formal or

less clear speaking style, indicating greater coarticulatory overlap between the consonant and vowel. Some of these differences have also been formulated in recent years in terms of so-called 'locus equations,' which provide one measure of the extent of the coarticulatory influence of vowels on consonants.

Motor Programming

Coordination of Muscle Activities

Speech production involves making precise and fast changes of vocal-tract configurations by orchestrating a multitude of muscle actions in the spatial as well as in the temporal domain. For the production of a bilabial closure, the articulators involved are the upper lip, the lower lip and the jaw carrying the lower lip upwards. For achieving the task of completely occluding the vocal tract with the lips, these articulators exhibit many 'degrees of freedom' in the amount to which each articulator contributes to the task; that is, in a vowel-bilabial-vowel sequence, a bilabial closure may be achieved with a range of different lip-jaw movements depending on contextual differences in the identities of the flanking vowels (see Saltzman and Munhall, 1989). Therefore, although the distance moved by the respective articulator varies with the context, the externally defined goal is achieved in a relatively invariant way. The involved muscle actions are generally assumed to be controlled and coordinated by organizing them into 'coordinative structures or synergies' instead of each muscle being controlled individually and continuously (see the section 'Context-Invariant Theories of Coarticulation' earlier in this article).

One very important property of speech production is that muscles and muscle groups unite in order to execute a specific task. This muscle linkage is not a hard-wired control of muscle compounds. It is defined functionally in a task-specific flexible manner with a fixed sequencing of individual muscle activities. Another phenomenon that can be explained by the organization of speech organs in coordinative structures is 'motor equivalence,' which refers to the finding that the same goal is reached in more than one way by the composite articulators compensating for each other (see Figure 4). For example, a bilabial closure can be achieved by moving the jaw, the lower lip, or the upper lip to a greater degree. Studies of 'perturbation' provide one of the most important experimental paradigms for studying 'compensatory behavior.' In studies of perturbation, an articulator or structure is either impeded for a longer stretch of time (static perturbation) or the ongoing motor act is perturbed suddenly and unexpectedly (dynamic perturbation). Static perturbations occur naturally, for example, when speaking with a pipe in the mouth; speakers produce near-normal speech despite the lower jaw being fixed by compensatory movements of other articulators. Similar results have been found experimentally by positioning bite-blocks of different sizes between the molars (see Lindblom *et al.*, 1979) or by inserting a thick artificial palate (e.g., Hamlet and Stone, 1976).

Figure 4 Possible combinations of upper lip, lower lip, and jaw movements for the achievement of a bilabial closure. Solid line: with jaw involvement; dotted line: with fixed jaw.

Dynamic perturbations can be induced by a small motor – in most experiments, attached to the jaw – that can be activated during some trials to generate a small load. A relatively new method is an inflatable artificial palate that dynamically changes its thickness and therefore the target region, e.g., for oral fricatives (see Honda *et al.*, 2002). The aim of applying these techniques is to determine (1) which articulators belong to a coordinative structure, (2) the task-specific spatial and temporal organization, (3) the biomechanical properties of the perturbed limb, and (4) the role of auditory and sensory feedback in the speech production process (see the next section in this article).

Responses to different kinds of perturbation have the following properties:

- Compensatory reactions are usually task-specific. In one of the most influential experiments, Kelso *et al.* (1984) recorded movements of jaw, upper and lower lip, and muscle activity of the tongue (EMG of genioglossus) during multiple repetitions of the utterances 'It's a /bæb/ again' or 'It's a /bæz/ again.' The mandibular closing movements towards the word-final consonants /b/ or /z/ were perturbed by a downward torque on a low percentage of trials. For the bilabial only, the lip muscles were activated in response to the perturbation, and the upper lip

compensated for the impeded lower-lip movement, whereas the tongue only reacted when the jaw movement towards the apical fricative /z/ was disrupted. These results give evidence for a short-term, task-specific organization of muscles into groups for producing a specific phoneme.

- Compensations are functional and successful, i.e., the intended target is usually achieved and the produced sound is intelligible. This shows that temporal and spatial amendments due to a load or structural perturbation are within acceptable limits.
- Compensatory movements are affected by the biomechanics and linkages of the system. For example, if the jaw is perturbed during sustained vowels, the same amount of force applied to the jaw causes larger displacements of the jaw in the vertical direction than in the horizontal (Shiller *et al.*, 2002) because of the limb-specific biomechanical stiffness.
- Compensations occur very rapidly: latencies amount to about 20 ms for responses to sudden perturbations; compensation occurs approximately at the second trial for producing a given sound in the case of static perturbation. On the one hand, the shortness of the reaction time suggests that the movement trajectories are not cognitively reorganized when disrupted, but that the reaction is instead triggered at a more peripheral neural control level. On the other hand, the compensatory movement is triggered too slowly to be controlled by a simple peripheral reflex involvement. Because the latencies also vary with the timing and the load of the perturbation, a reflex-like reaction can be excluded. The fast reaction time and successful compensation even at the first perturbed trial suggest that sensory information from the periphery plays a major role in ensuring that articulatory targets are achieved. An alternative explanation assumes that the short reaction time is achieved by regulating properties of the neural linkages between the composite articulators of a synergy (Gomi *et al.*, 2002).

The Role of Feedback

The above findings on perturbation suggest that speech is monitored online using feedback from sensory information. Online sensory information is not included as a basic control mechanism in 'motor program theories' (for an excellent summary of speech production models, see Kent *et al.*, 1996), which assume that a ready-made plan of an utterance is executed by the speech organs rather in the same way that computer programs are executed, without any immediate feedback required (when a program is executed without any feedback, it is known as an 'open loop' system).

In contrast, in 'feedback systems,' information from the periphery regarding the output of the system is used to modify the system's behavior to ensure that movement goals are achieved. Feedback is available for the speaker from auditory, tactile, and proprioceptive receptors. For example, assuming the tongue is the structure to be controlled, the input to the feedback model is the neural command to the tongue muscle, and the output is the resulting tongue movement. If there is a difference between the intended and the actual tongue movement, this sensory information is received by a control center after a small time delay, and then a motor command is sent to correct the discrepancy. The term 'closed loop' implies that once the command to move has been issued, no further action of the command center is needed, because feedback modifies the input command to control the outcome. These models have been challenged on several grounds: apart from evidence that the sensory feedback (auditory as well as tactile) is probably too slow for online monitoring of the ongoing movement, it has also been found that a disruption of feedback channels (trigeminal nerve block, topical anesthesia, and noise masking) affects the production of speech only very slightly so that 'online continuous feedback' might only play a direct role either when the motor system is unexpectedly perturbed or in motor learning.

That short latency proprioceptive feedback loops are likely to contribute to speech movement production in a 'discontinuous' manner has been shown by means of a 2-D biomechanical tongue model by Payan and Perrier (1997) (based on the 'Equilibrium Point Hypothesis' of Feldman (1966)). Articulatory targets are not planned in, for example, a constriction-based space but as threshold lengths of the involved muscles. Because the precise trajectory of the movement between two targets in this theoretical framework is a consequence of the mechanical and dynamical properties of the speech apparatus, online monitoring via feedback is only required at the target phases.

'Feedforward' models, often combined with feedback loops, have been proposed because they allow faster error correction than pure feedback systems. In these models, predictive adjustments at the periphery are made by means of an internal representation of the relations between motor commands and physical (proprioceptive, articulatory, or auditory) outputs (for example, there might be a neural representation of the expected auditory signal generated by current vocal-tract states before speech production is executed). Therefore, the difference between feedback and feedforward models is that whereas feedback models make use of sensory information for

correction during or after a planned speech event, in feedforward systems a prediction is made of the feedback that is expected from a set of motor commands (for an extensive overview on internal models for general motor control, see Jordan and Wolpert (1999)). Based on this prediction, a correction can be made to the motor commands before they are executed.

Even so, it is generally agreed that 'auditory feedback' is far too slow to play a crucial role in online error correction of the relatively quick speech movements. Several experiments have shown that after some adaptation time, auditory feedback leads to slightly more acceptable productions and improves the quality of compensations due to unexpected perturbation as compared to masked or delayed auditory feedback.

The Nature of the Motor Plan/Target Because the units of the speech motor program are not directly observable, their properties can only be indirectly inferred. An important issue in the ongoing discussion is whether these units are represented in the brain in different modalities (e.g., auditory, orosensory, and postural spaces) or in only one mode. Closely related to this debate is the question of what kind of information (e.g., visual, auditory, sensory) is necessary for an infant to establish these units.

The models of 'articulatory phonology' and the 'direct realist theory' discussed earlier reject the notion that speech production and perception use different modalities. Because the articulatory gesture serves as the 'common currency' for the communication between the listener and the speaker (see Goldstein and Fowler, 2003), the linguistic and phonological codes "are not lost in the vocal tract and reconstituted by the perceiver," and no translation is necessary between multimodal representations.

Articulatory phonology and direct realist theory has been criticized on several grounds, including that it cannot explain how infants acquire speech without an internal representation or mapping between the motor actions of the vocal tract and the acoustical consequences of these actions. The emergence of phonological categories and their combination into words from the babbling stage would seem to be hampered without the influence of an auditory model of persons who have already mastered speech acquisition. The importance of auditory feedback in speech acquisition is evident from the difficulties deaf children have in producing intelligible speech, while postlingually acquired hearing loss in adulthood affects the quality and stability of already acquired sound categories only very slightly (Guenther and Perkell, 2004).

Motor learning with recourse to auditory reinforcement was successfully simulated by the neural network DIVA model (Directions Into Velocities of Articulators), which translates orosensory goals into movements (see e.g., Guenther, 2003; Guenther and Perkell, 2004). During the babbling phase, synaptic weights are tuned according to the tactile, proprioceptive, and auditory feedback provided by randomized movements. In a first stage, the mapping between the orosensory space and articulatory movements is learned by random movements of the speech articulators, which causes orosensory feedback. The resulting mapping is closely related to coordinative structures and can therefore explain compensatory behavior; raising the tongue tip causes proprioceptive sensations in the tongue and jaw muscles and tactile sensations at the alveolar ridge. In this way, the baby learns that a close contact between the tongue tip and the alveolar ridge can be achieved by different degrees of tongue and jaw involvement, i.e., motor equivalence. The second stage involves the establishment of the speech sound map, which contains multidimensional auditory target regions (rather than points) for the speech sounds that the baby has encountered so far. When the babbling infant is producing a speech sound, the projections between the auditory and orosensory dimensions are continuously readjusted during the learning process to achieve a target region for acceptable variants of given phoneme, e.g., with a wide range of tongue height but a small range of bilabial aperture variation for the bilabial stop. Once these mappings are established, online auditory feedback is no longer needed, but the targets of this model are defined in a planning space with auditory and orosensory dimensions. Planning a movement towards an orosensory goal involves the computation of articulatory changes to carry out the intended changes in the auditory parameters, i.e., planning occurs in the auditory domain.

In contrast to the DIVA model, the perception and production of articulatory gestures in articulatory phonology is achieved without any recourse to auditory feedback. Infants first learn to distinguish between the actions of discrete organs and imitate these actions from adults. Here the puzzle is how infants can imitate actions such as tongue protrusion. They cannot see their own tongue, and they cannot feel the tongue of the adult. Goldstein and Fowler (2003) argue that imitation of an action can only be achieved by a baby because he or she perceives the distal actions, i.e., extracts the distal events from information acquired optically or acoustically, and imitates them. Information from acoustics without articulation is ambiguous and does not provide enough information for motor learning. Moreover,

the acoustics as well as the motor commands are very different for an adult with a large vocal tract and a baby, but the gestures, e.g., tongue dorsum backing, are the same for an adult and an infant. Because gestures are the common currency of perception and production, no mapping between representations is needed. Whether acoustical information is important for specifying various types of phonological units is still a matter of discussion between the proponents of the two theories, and as Goldstein and Fowler (2003) point out, "the final experiments on this question have not yet been performed."

Overview and Motivation

The recent algorithmic advances in the field of automatic speech recognition (ASR) together with progress in natural language understanding and speech synthesis have allowed the deployment of many automatic systems for speech-based human–computer interaction. Of course, these systems require highly accurate ASR to achieve successful task completion and user satisfaction, which in general is attainable in relatively quiet acoustic environments and for low-to medium-complexity recognition tasks. However, current ASR still lags in performance compared to humans, as discussed in Lippmann (1997), and lacks robustness to acoustic noise, its accuracy degrading significantly, especially under acoustic channels or environments mismatched to its training data.

To improve ASR, a number of researchers have recently been investigating additional signals as a complementary speech information source to the acoustic signal produced by the human vocal tract and traditionally used in ASR systems. For example, vocal cord vibration can be captured by a throat microphone, as in Graciarena *et al*. (2003), whereas a bone-conductive microphone can capture speech-induced skull vibration, as discussed in Zhang *et al*. (2004). By far, however, most attention has focused on exploiting speech information present in the video of the speaker's mouth region. Such signal is clearly not affected by acoustic noise, and is often available in recordings, or can be captured in certain practical scenarios of human–computer interaction by desktop computers, 'intelligent kiosks,' inside automobiles, 'smart rooms,' or when wearing specially designed audio-visual headsets as the one described by Huang *et al*. (2004). Employing visual information for ASR is known as automatic lipreading, and more often as automatic speechreading, since much speech information is located in the whole lower face and not only in the lips. In practice, the visual channel is used to augment the acoustic signal, resulting in audio-visual ASR (AVASR).

Research interest in AVASR has been motivated by the bimodality of human speech perception (Campbell *et al*., 1998). Indeed, humans combine audio and visual information in deciding what has been spoken, which is especially noticeable in noisy environments, where the visual benefit to speech intelligibility has been quantified in studies such as by Sumby and Pollack (1954). The bimodality of speech

Figure 1 The main processing blocks of an audio-visual automatic speech recognition system. Visual feature extraction and audio-visual integration represent added components, compared to audio-only speech recognition. Different approaches for their design are reviewed in this article.

perception also becomes clear in the McGurk effect, first demonstrated by McGurk and MacDonald (1976) (see also Massaro and Stork, 1998): for example, when the spoken sound /ba/ is superimposed on video of a person uttering /ga/, most people perceive the sound /da/. In addition, visual information is particularly important to the hearing impaired, who typically lipread well. There are three key reasons why vision benefits human speech perception (Summerfield, 1987): it helps with source localization, it provides speech segmental information, and most importantly, the video contains information about the place of articulation. This is complementary to the acoustic information, as it helps disambiguate phonemes with the same manner of articulation, which therefore are difficult to tell apart by acoustics alone. For example, the unvoiced consonants /p/ and /k/ can be easily distinguished visually, because the first is a bilabial and the second a velar, i.e., their production involves different visible articulator movements of the lips and tongue, respectively.

It is therefore not surprising that exploiting visual speech information in ASR has received significant interest. The first AVASR system reported in the literature was built by Petajan (1984). He used image thresholding to obtain binary mouth images from the input video, which were then analyzed to extract mouth height, width, and other features, subsequently used as visual input to ASR. He was then able to classify isolated words within a small vocabulary set, uttered by a single speaker, by using these visual features and dynamic time warping (Rabiner and Juang, 1993). For joint audio-visual recognition, Petajan employed the visual system as a means to rescore *N*-best word hypotheses of audio-only ASR.

Since then, a number of researchers have developed AVASR systems of increasing complexity. Their systems vary in a number of areas, most importantly the visual feature extraction, the choices of speech classes and ASR classifier used, as well as the approach used in combining the visual with the acoustic features (see also Figure 1). The reported systems are developed on a variety of databases and recognition tasks, ranging from single-speaker, nonsense syllable or small-vocabulary isolated-word recognition to speaker-independent, large-vocabulary continuous speech recognition. A review of the most commonly adopted techniques in these systems can be found in Stork and Hennecke (1996); Chen and Rao (1998); Chibelushi *et al.* (2002); and Potamianos *et al.* (2003). In the remainder of the article, we briefly discuss the main approaches in the design of the AVASR components.

Feature Extraction

The first critical issue in the design and implementation of AVASR systems is the choice of visual features and their robust extraction from video. Visual speech information is mostly contained in the speaker's mouth region; therefore typically the visual features consist of appropriate representations of mouth appearance and/or shape. Of course, for visual feature extraction to commence, first the speaker's face has to be located in the video, followed by the detection of the mouth region and possibly of the lip contours, as well as their appropriate normalization.

Face detection has attracted significant interest in the literature, with a number of different techniques applied. In most AVASR systems, statistical approaches are employed to classify regions of the video as belonging to the face or nonface classes (for example, see Sung and Poggio, 1998). These techniques can be further enhanced to detect facial features such as lip points, nostrils, and eyes, that can help locate the mouth region of interest (ROI), and to estimate the head pose in order to provide ROI normalization (Potamianos *et al.*, 2003).

Once the ROI is located, a number of algorithms can be used to obtain lip contour estimates, if such contours are required for visual feature extraction. Some popular methods for this task are snakes (elastic

curves represented by control points) and templates (parametric curves, such as parabolas), both fitted to the desired characteristics of the mouth image by an iterative minimization algorithm (Aleksic *et al.*, 2002). Alternatively, statistical models of the mouth shape, such as active shape models, or joint statistical models of the mouth shape and appearance (the so-called active appearance models) can be used for estimating the contours. These models are obtained by performing a principal component analysis (PCA) on vectors containing the coordinates of a training set of points that lie on the shapes of interest, with tracking achieved by an iterative fitting algorithm (Dupont and Luettin, 2000).

Following the above steps, visual features can be extracted from the speaker's video. Such features capture the mouth ROI appearance, the mouth shape, or both (see also Figure 2). In the appearance-based approach, the low-level representation of the mouth ROI pixels is considered as informative for speechreading, and placed into a vector. Subsequently, a number of image compression or pattern classification techniques are applied to it, in order to reduce its dimensionality; for example, PCA (Bregler and Konig, 1994), the discrete cosine transform (Potamianos *et al.*, 2003), linear discriminant analysis, etc. In contrast, the shape-based approach assumes that most speechreading information is contained in the shape of the speaker's lips (inner and outer contours), or more generally in the face contours. This information is typically represented by geometric- or model-based features. The former are typically the height, width, perimeter, and area within the contour, as in Adjoudani and Benoit (1996), whereas the latter are obtained in conjunction with one of the parametric or statistical lip-tracking algorithms discussed in the previous paragraph (snake radial vectors, parabola parameters, active shape model), as in Dupont and Luettin (2000), for example. Often, appearance and shape features are combined by simply concatenating them, or by using a joint statistical model.

Unfortunately, little work exists in the literature that compares the AVASR performance of the appearance and shape-based approaches. In general though, appearance-based features avoid lip contour tracking, which is computationally expensive and unfeasible for low-quality videos, but are believed to be more speaker-dependent than shape-based features.

The extracted visual features are often postprocessed in order to improve ASR performance; for example, dynamic speech information can be captured if the feature vector is augmented by its first- and second-order temporal derivatives. Furthermore,

Figure 2 Examples of visual features used in the literature for automatic speechreading and audio-visual speech recognition. Appearance-based, geometric, parametric, and statistical shape-based features are schematically depicted.

interpolation of the visual features from the video rate (typically 25 or 30 Hz) to the acoustic feature rate is often employed to allow easy audio-visual integration. The acoustic features are usually generated at 100 Hz, and in most AVASR systems reported in the literature, they consist of mel-frequency cepstral or linear prediction coefficients (Rabiner and Juang, 1993).

Recognition

The second critical issue in the design of AVASR systems is the integration (fusion) of the acoustic and visual features into the recognition process. This should be designed in a way to ensure that the resulting system achieves a recognition performance superior to its single-modality counterparts, i.e., audio-only and visual-only ASR, and hopefully by a large margin in order to justify the added complexity of visual capture and processing. A number of audio-visual fusion techniques have been considered in the literature for this purpose and are described here. Of course, their AVASR implementation varies, depending among others on the choice of speech classes and the classifier used in the recognition process. Common choices are discussed next. Finally, examples of successful application of these techniques in AVASR are presented at the end of this section.

Visual Speech Classes and Classifiers for ASR

Current state-of-the-art ASR systems typically use sub-phonetic classes as the basic recognition units. Such classes are obtained by decision-tree modeling of the neighboring phonetic context (Rabiner and Juang, 1993), and in most large-vocabulary systems are in the order of a few thousand.

The same classes can of course be readily used in visual-based ASR. However, it is worth mentioning that the video signal contains significantly less speech information than noise-free audio, since not all phonemes are distinguishable using visual information. As a matter of fact, only clusters of phonemes, referred to in the literature as visemes, can be visually distinguished from each other. Indeed, the approximately 42 phonemes of American English are grouped into about 15 visemes, for example one of which is the bilabial viseme {/b/, /m/, /p/} (Stork and Hennecke, 1996). The members of this group look visually the same, as their production involves identical lip movement. This fact has motivated several researchers to use visemic or subvisemic classes for automatic speechreading. However, the majority of AVASR works assume identical classes for both acoustic and visual system components, thus making their integration easier.

In ASR the classes of interest are 'hidden,' observed only through a sequence of speech informative features. To obtain these classes, and subsequently the sequence of spoken words, statistical classifiers are used. In most systems, these are hidden Markov models (HMMs), with their class-conditional probability distributions – also known as 'emission' or observation probabilities – being Gaussian mixture models with diagonal covariances (Rabiner and Juang, 1993). Most researchers use such HMMs in AVASR, but alternative models are also often employed, such as artificial neural networks (Heckmann *et al.*, 2002), support vector machines, and HMMs with discrete observation probabilities.

Audio-Visual Integration

As mentioned above, various information fusion algorithms have been considered in the literature for AVASR. Although their implementation varies depending on the choices of features, classes, and classifiers used, one can broadly group them into feature fusion and classifier fusion methods (see also Figure 3).

Feature fusion techniques employ a single classifier that operates on multimodal feature vectors, such as

Figure 3 HMM-based feature and classifier fusion for audio-visual integration.

Figure 4 Example video frames of four audio-visual databases collected at IBM Research, left-to-right: using a specially designed audio-visual headset (Huang *et al.*, 2004), and color cameras in studio-like conditions, offices, and cars.

Figure 5 Examples of visual modality benefit to ASR for multiple speaker recognition of connected digit strings for the four databases of **Figure 4**, under noisy audio. Visual-only, audio-only, and audio-visual word error rates (WER), %, are shown.

the concatenated vector of time-synchronous audio and visual features, or any transformation of them in an appropriate space, as for example the 'dominant' and 'motor' recording fusion discussed by Teissier *et al.* (1999), or the enhancement techniques proposed in Girin *et al.* (2000). In contrast, classifier fusion algorithms utilize the output of the audio and visual classifiers to jointly estimate the hidden speech classes of interest. Typically, this is achieved by linearly combining the observation log-likelihoods of the individual classifiers into a joint audio-visual classification score, using appropriate weights that capture the reliability of each single-modality classifier. Such a combination typically occurs 'in parallel' using the mechanism of the so-called multistream HMM. Alternative approaches also exist, for example combining the classifiers 'in cascade,' by using one or both modalities to rescore the top N ranked outputs of the most reliable modality. One such approach is the discriminative model combination algorithm.

Most practical AVASR systems use the multistream HMM as a model for audio-visual fusion. In most cases, the emission probability combination occurs at the frame level, or equivalently the class level (i.e., HMM state). Some researchers have also considered combination at a coarser level, namely at the phone, syllable, or even the word level. Such combination can easily be accommodated using appropriate extensions to the multistream HMM framework. Typically, two single-modality three-state phone HMMs are combined, giving rise to a nine-state composite HMM, also known as a product or coupled HMM (Nefian *et al.*, 2002). In both cases, HMM parameters can be easily obtained using maximum-likelihood estimation or discriminative training, as in traditional HMMs (Rabiner and Juang, 1993). Of particular interest is the estimation of the weights that are used to combine the probabilities of the two streams of interest. Such can be derived by discriminative training, or by seeking optimal performance of the combined system on a held-out set. The weights can be globally set for an entire database, or vary based on local estimates of the audio and visual signal quality, and/or reliability measures of the two single-stream classifiers.

Results

Numerous works report AVASR results on various audio-visual databases. We briefly mention the work at IBM, where a number of bimodal corpora have been collected and performance of audio vs. audio-visual ASR has been benchmarked. Four such representative sets are depicted in **Figure 4**, collected in various domains, and using different sensors. Examples of typical performance gains achieved in noisy audio conditions due to the inclusion of the visual modality into ASR are depicted in **Figure 5**. These gains approximately correspond to 69%, 58%, 41%, and 37%, relative reduction in word error rate for the four domains (left-to-right); in all cases, connected digit strings are recognized. Notice that the visual-only performance degrades as the visual channel becomes more challenging (headset to car domain).

Summary and Discussion

In this article, we reviewed the basic techniques used for incorporating visual speech information into automatic speech recognition. We particularly focused on the issues of visual processing and audio-visual integration, which constitute two additional components over traditional audio-only systems. We also presented examples of recognition results that demonstrate the significant benefit of the visual modality to speech recognition.

The field of AVASR is relatively young, but nevertheless significant progress has been accomplished over the past 20 years. Concerning the practical

deployment of this technology, several obstacles have been slowly lifting, with audio-visual systems starting to exhibit real-time performance and improved robustness. Nevertheless, open research issues still remain in both visual processing and audio-visual integration components.

Finally, it is especially interesting to note that many of the algorithms described in this article are directly applicable to a number of other audio-visual speech technologies: for example, speech synthesis, emotion recognition, speech activity detection, speaker recognition, and speaker localization, among others (Chen and Rao, 1998; Yehia *et al*., 1998; Cosatto and Graf, 2000; Aleksic and Katsaggelos, 2005). These technologies are key to human–computer interaction, and incorporating the visual modality – whenever available – promises to make such interaction more natural and robust.

spoken speech, and respond as if it were an intelligent being. This anthropomorphism of HAL made the general public aware of the potential of intelligent machines. In the famous *Star Wars* saga, George Lucas extended the abilities of intelligent machines by making them mobile as well as intelligent and the droids such as R2D2 and C3PO were able to speak naturally, recognize and understand fluent speech, and move around and interact with their environment, with other droids, and with the human population at large. More recently (in 1988), in the technology community, Apple Computer created a vision of speech technology and computers for the year 2011, called Knowledge Navigator, which defined the concepts of a Speech User Interface (SUI) and a Multimodal User Interface (MUI) along with the theme of intelligent voice-enabled agents. This video had a dramatic effect in the technical community and focused technology efforts, especially in the area of visual talking agents.

Today speech technologies are commercially available for a limited but interesting range of tasks. These technologies enable machines to respond correctly and reliably to human voices, and provide useful and valuable services. While we are still far from having a machine that converses with humans on arbitrary topics like another human, many important scientific and technological advances have taken place, bringing us closer to the Holy Grail of machines that recognize and understand fluently spoken speech. This article attempts to provide a historic perspective on key inventions that have enabled progress in speech recognition and language understanding and briefly reviews several technology milestones as well as enumerating some of the remaining challenges that lie ahead of us.

From Speech Production Models to Spectral Representations

Attempts to develop machines to mimic a human's speech communication capability appear to have started in the second half of the 18th century. The early interest was not on recognizing and understanding speech, but instead on creating a speaking machine, perhaps due to the readily available knowledge of acoustic resonance tubes that were used to approximate the human vocal tract. In 1773 the Russian scientist Christian Kratzenstein, a professor of physiology in Copenhagen, succeeded in producing vowel sounds using resonance tubes connected to organ pipes (Kratzenstein, 1782: 358–380). In 1791 Wolfgang von Kempelen in Vienna constructed an Acoustic-Mechanical Speech Machine (Dudley and Tarnoczy, 1950) and in the mid-1800s Charles Wheatstone (Wheatstone, 1879) built a version of von Kempelen's speaking machine using resonators made of leather, the configuration of which could be altered or controlled with a hand to produce different speech-like sounds, as shown in Figure 2.

During the first half of the 20th century, work by Fletcher (Fletcher, 1922) and others at Bell Laboratories documented the relationship between a given speech spectrum (which is the distribution of power of a speech sound across frequency), and its sound characteristics as well as its intelligibility to a human listener. In the 1930s Homer Dudley, influenced greatly by Fletcher's research, developed a speech synthesizer called the VODER (Voice Operating Demonstrator) (Dudley and Watkins, 1939), which was an electrical equivalent (with mechanical control) of Wheatstone's mechanical speaking machine. Figure 3 shows a block diagram of Dudley's VODER,

Figure 2 Wheatstone's version of von Kempelen's speaking machine (from Flanagan, 1972).

Figure 3 A block schematic of Homer Dudley's VODER (From Dudley *et al.,* 1939).

Figure 4 The VODER at the 1939 World Fair in New York City.

which consisted of a wrist bar for selecting either a relaxation oscillator output or noise as the driving signal, and a foot pedal to control the oscillator frequency (the pitch of the synthesized voice). The driving signal was passed through ten bandpass filters whose output levels were controlled by the operator's fingers. These ten bandpass filters were used to alter the power distribution of the source signal across a frequency range, thereby determining the characteristics of the speechlike sound at the loudspeaker. Thus to synthesize a sentence, the VODER operator had to learn how to control and 'play' the VODER so that the appropriate sounds of the sentence were produced. The VODER was demonstrated at the World's Fair in New York City in 1939 (shown in Figure 4) and was considered an important milestone in the evolution of speaking machines.

The pioneering work of Harvey Fletcher and Homer Dudley firmly established the importance of the signal spectrum for reliable identification of the phonetic nature of a speech sound. Following the convention established by these two outstanding scientists, most modern systems and algorithms for speech recognition are based on the concept of measurement of the (time-varying) speech power spectrum (or its variants such as the cepstrum), in part due to the fact that measurement of the power spectrum from a signal is relatively easy to accomplish with modern digital signal processing techniques.

Early Automatic Speech Recognizers

Early attempts to design systems for automatic speech recognition were mostly guided by the theory of acoustic-phonetics, which describes the phonetic elements of speech (the basic sounds of the language) and tries to explain how they are acoustically realized in a spoken utterance. These elements include the phonemes and the corresponding place and manner of articulation used to produce the sound in various phonetic contexts. For example, in order to produce a

Figure 5 Block schematic of digit recognizer circuits (from Davis *et al.,* 1952).

steady vowel sound, the vocal cords need to vibrate (to excite the vocal tract), and the air that propagates through the vocal tract results in sound with natural modes of resonance similar to what occurs in an acoustic tube. These natural modes of resonance, called the *formants* or *formant frequencies,* are manifested as major regions of energy concentration in the speech power spectrum. In 1952 Davis *et al.,* of Bell Laboratories built a system for isolated digit recognition for a single speaker (1952) using the formant frequencies measured (or estimated) during vowel regions of each digit. Figure 5 shows a block diagram of the digit recognizer developed by Davis *et al.,* and Figure 6 shows plots of the formant trajectories along the dimensions of the first and the second formant frequencies for each of the ten digits, 1–9 and 0, respectively. These trajectories, in which time was an implicit parameter, served as the reference pattern for determining the identity of an unknown digit utterance as the best matching digit.

In other early recognition systems of the 1950s, Olson and Belar of RCA Laboratories built a system to recognize 10 syllables of a single talker (Olson and Belar, 1956) and at MIT Lincoln Lab, Forgie and Forgie built a speaker-independent 10-vowel recognizer (Forgie and Forgie, 1959). In the 1960s, several Japanese laboratories demonstrated their capability of building special-purpose hardware to perform a speech recognition task. Most notable were the vowel recognizer of Suzuki and Nakata at the Radio Research Lab in Tokyo (Suzuki and Nakata, 1961), the phoneme recognizer of Sakai and Doshita at Kyoto University (Sakai and Doshita, 1962), and the digit recognizer of NEC Laboratories (Nagata *et al.,* 1963). The work of Sakai and Doshita involved the first use of a speech segmenter for analysis and recognition of speech in different portions of the input utterance. In contrast, an isolated digit recognizer implicitly assumed that the unknown utterance contained a complete digit (and no other speech sounds or words) and thus did not need an explicit segmenter. Kyoto University's work could be considered a precursor to a continuous speech recognition system.

In another early recognition system Fry and Denes, at University College in England, built a phoneme recognizer to recognize 4 vowels and 9 consonants (Fry and Denes, 1959). By incorporating statistical information about allowable phoneme sequences in

Figure 6 Photographs of formant 1 vs. formant 2 presentation of the digits. (from Davis *et al.,* 1952).

English, they increased the overall phoneme recognition accuracy for words consisting of two or more phonemes. This work marked the first use of *statistical syntax* (at the phoneme level) in automatic speech recognition.

An alternative to the use of a speech segmenter was the concept of adopting a *non-uniform time scale* for aligning speech patterns. This concept started to gain acceptance in the 1960s through the work of Tom Martin at RCA Laboratories (Martin *et al.,* 1964) and Vintsyuk in the Soviet Union (Vintsyuk, 1968). Martin recognized the need to deal with the temporal nonuniformity in repeated speech events and suggested a range of solutions, including detection of utterance endpoints, which greatly enhanced the reliability of the recognizer performance (Martin *et al.,* 1964). Vintsyuk proposed the use of dynamic programming for time alignment between two utterances in order to derive a meaningful assessment of their similarity (Vintsyuk, 1968). His work, though largely unknown in the West, appears to have preceded that of Sakoe and Chiba (1978) as well as others who proposed more formal methods, generally known as dynamic time warping, in speech pattern matching. Since the late 1970s, mainly due to the publication by Sakoe and Chiba, dynamic programming, in numerous variant forms (including the Viterbi algorithm, Viterbi 1967, which came from the communication theory community), has become an indispensable technique in automatic speech recognition.

Technology Drivers since the 1970s

In the late 1960s, Atal and Itakura independently formulated the fundamental concepts of Linear Predictive Coding (LPC) (Atal and Hanauer, 1971; Itakura and Saito, 1970), which greatly simplified the estimation of the vocal tract response from speech waveforms. By the mid-1970s, the basic ideas of applying fundamental pattern recognition technology to speech recognition, based on LPC spectral estimation methods, were proposed by Itakura (1975), Rabiner and Levinson (1979), and others.

Also during this time period, based on his earlier success at aligning speech utterances, Tom Martin founded Threshold Technology, the first company to attempt to commercialize speech recognition technology, and developed the first real ASR product called the VIP–100 System. The system was only used in a few simple applications, such as by television faceplate manufacturing firms (for quality control) and by FedEx (for package sorting on a conveyor belt), but its main importance was the way it influenced the Advanced Research Projects Agency (ARPA) of the U.S. Department of Defense to fund the Speech Understanding Research (SUR) program during the early 1970s. Among the systems built by the contractors of the ARPA program was Carnegie Mellon University's (CMU) Harpy (Lowerre, 1986), which was shown to be able to recognize speech using a vocabulary of 1011 words with reasonable accuracy. One particular contribution from the Harpy system was the concept of doing a graph search, where the speech recognition language is represented as a connected graph derived from lexical representations of words, with syntactical production rules and word boundary rules. In the Harpy system, the input speech was first analyzed to produce a time-dependent parametric representation and then segmented into sounds. The segmented parametric representation of speech was then subjected to phone template matching using the Itakura distance (Itakura, 1975). The

graph search, based on a beam search algorithm, compiled, hypothesized, pruned, and then verified the recognized sequence of words (or sounds) that satisfied the knowledge constraints with the highest matching score (smallest distance to the reference patterns). The Harpy system was perhaps the first to take advantage of a finite state network to reduce computation and efficiently determine the closest matching string. However, methods that optimized the finite state network (FSN) (for performance as well as to eliminate redundancy) did not come about until the early 1990s (Mohri, 1997).

Other systems developed under DARPA's SUR program included CMU's Hearsay(-II) and BBN's HWIM (Klatt, 1977). Neither Hearsay-II nor HWIM (Hear What I Mean) met the DARPA program's performance goal at its conclusion in 1976. However, the approach proposed by Hearsay-II of using parallel asynchronous processes that simulate the component knowledge sources in a speech system was a pioneering concept. The Hearsay-II system extended sound identity analysis (to higher level hypotheses) given the detection of a certain type of (lower level) information or evidence, which was provided to a global 'blackboard' where knowledge from parallel sources was integrated to produce the next level of hypothesis. BBN's HWIM system, on the other hand, was known for introducing interesting new ideas such as a lexical decoding network incorporating sophisticated phonological rules (aimed at phoneme recognition accuracy), its handling of segmentation ambiguity by a lattice of alternative hypotheses, and the concept of word verification at the parametric level. Another system worth noting of the time was the DRAGON system by Jim Baker, who moved to Massachusetts to start a company with the same name in the early 1980s.

In parallel to the ARPA-initiated efforts, two broad directions in speech recognition research started to take shape in the 1970s, with IBM and AT&T Bell Laboratories essentially representing two different schools of thought as to the applicability of automatic speech recognition systems for commercial applications.

IBM's effort, led by Fred Jelinek, was aimed at creating a voice-activated typewriter (VAT), the main function of which was to convert a spoken sentence into a sequence of letters and words that could be shown on a display or typed on paper (Jelinek *et al.,* 1975). This type of speech recognition task is generally referred to as *transcription.* The recognition system, called Tangora, was essentially a speaker-dependent system (i.e., the typewriter had to be trained by each user). The technical focus was on the size of the recognition vocabulary (with dictation in office correspondence as the primary application), and the structure of the language (the grammar). IBM addressed the issue of grammar from a statistical decoding perspective; statistical syntactical rules were used to describe how likely, in a probabilistic sense, was a sequence of language symbols (e.g., phonemes or words) that could appear in the speech signal. The set of statistical grammatical or syntactical rules was called a *language model,* of which the *n-gram* model, which defined the probability of occurrence of an ordered sequence of n words, was the most frequently used variant. Although both the n-gram language model and a traditional grammar are manifestations of the rules of the language, their roles were fundamentally different. The n-gram model, which characterized the word relationship within a span of n words, was purely a convenient and powerful statistical representation of a grammar. Its effectiveness in guiding a word search for speech recognition, however, was strongly validated by the famous word game of Claude Shannon (1948) that involved a competition between a human and a computer. In this competition both the computer and the human are asked to sequentially guess the next word in an arbitrary sentence. The human guesses based on native experience with language; the computer uses the accumulated word statistics to make its best guess based on maximum probability from the estimated word frequencies. It was shown that once the span of the words, n, exceeded three, the computer was very likely to win (make better guesses as to the next word in the sequence) over the human player. Since their introduction in the 1980s, the use of n-gram language models, and their variants, has become indispensable in large vocabulary speech recognition systems.

At AT&T Bell Laboratories, the goal of the research program was to provide automated telecommunication services to the public, such as voice dialing and command and control for routing of phone calls. These automated systems were expected to work well for a vast population (tens of millions) of talkers. The focus at Bell Laboratories was in the design of a speaker-independent system that could deal with the acoustic variability intrinsic in the speech signals coming from many different talkers, often with notably different regional accents. This led to the creation of a range of speech clustering algorithms for creating word and sound reference patterns (initially templates but ultimately statistical models) that could be used across a wide range of talkers and accents. Furthermore, research to understand and to control the acoustic variability of various speech representations across talkers led to the study of a range of spectral distance measures (e.g., the Itakura distance [Itakura, 1975] and statistical modeling

techniques [Juang *et al.* 1986]) that produced sufficiently rich representations of the utterances from a vast population. (As will be elaborated in the next section, the technique of mixture density hidden Markov models [Juang, 1985; Lee *et al.,* 1990] has since become the prevalent representation of speech units for speaker independent continuous speech recognition.) Since applications such as voice dialing and call routing usually involved only short utterances of limited vocabulary and consisted of only a few words, there was an emphasis of the research at Bell Laboratories on what is generally called the *acoustic model* (the spectral representation of sounds or words) over the language model (the representation of the grammar or syntax of the task). Also, of great importance in the Bell Laboratories' approach was the concept of *keyword spotting* as a primitive form of speech understanding (Wilpon, 1990). The technique of keyword spotting aimed at detecting a keyword or a key phrase of some particular significance that was embedded in a longer utterance where there was no semantic significance to the other words in the utterance. The need for such keyword spotting was to accommodate talkers who preferred to speak in natural sentences rather than using rigid command sequences when requesting services (i.e., as if they were speaking to a human operator). For example, a telephone caller requesting a credit card charge might speak the sentence 'I'd like to charge it to my credit card' rather than just say 'credit card.' In a limited domain application, the presence of the key-phrase 'credit card' in an otherwise naturally spoken sentence was generally sufficient to indicate the caller's intent to make a credit card call. The detected keyword or key-phrase would then trigger a prescribed action (or sequence of actions) as part of the service, in response to the talker's spoken utterance. The technique of keyword spotting required extension of the usual pattern recognition paradigm to one that supported hypothesis testing.

The IBM and AT&T Bell Laboratories approaches to speech recognition both had a profound influence in the evolution of human-machine speech communication technology of the last two decades. One common theme between these efforts, despite the differences, was that mathematical formalism and rigor started to emerge as distinct and important aspects of speech recognition research. While the difference in goals led to different realizations of the technology in various applications, the rapid development of statistical methods in the 1980s, most notably the hidden Markov model (HMM) framework (Jelinek, 1976; Levinson *et al.,* 1983), caused a certain degree of convergence in the system design. Today, most practical speech recognition systems are based on the statistical framework and results developed in the 1980s, with significant additional improvements in the 1990s.

Technology Directions in the 1980s and 1990s

Speech recognition research in the 1980s was characterized by a shift in methodology from the more intuitive template-based approach (a straightforward pattern recognition paradigm) toward a more rigorous statistical modeling framework. Although the basic idea of the hidden Markov model (HMM) was known and understood early on in a few laboratories (e.g., IBM and the Institute for Defense Analyses (IDA) [Ferguson, 1980]), the methodology was not complete until the mid-1980s and it wasn't until after widespread publication of the theory (Levinson *et al.,* 1983; Ferguson, 1980) that the hidden Markov model became the preferred method for speech recognition. The popularity and use of the HMM as the main foundation for automatic speech recognition and understanding systems has remained constant over the past two decades, especially because of the steady stream of improvements and refinements of the technology.

The hidden Markov model, which is a doubly stochastic process, models the intrinsic variability of the speech signal (and the resulting spectral features) as well as the structure of spoken language in an integrated and consistent statistical modeling framework (Rabiner and Juang, 2004). As is well known, a speech signal is inherently highly variable (due to variations in pronunciation and accent, as well as environmental factors such as reverberation and noise). When people speak the same word, the acoustic signals are not identical (in fact they may even be remarkably different at the acoustic level), even though the underlying linguistic structure, in terms of the pronunciation, syntax and grammar, may (or may not) remain the same. The formalism of the HMM is a probability measure that uses a Markov chain to represent the linguistic structure and a set of probability distributions to account for the variability in the acoustic realization of the sounds in the utterance. Given a set of known (text-labeled) utterances, representing a sufficient collection of the variations of the words of interest (called a training set), one can use an efficient estimation method, called the Baum-Welch algorithm (Baum, 1972), to obtain the 'best' set of parameters that define the corresponding model or models. The estimation of the parameters that define the model is equivalent to training and learning. The resulting model is then used to provide an indication of the likelihood (probability) that an

unknown utterance is indeed a realization of the word (or words) represented by the model. The probability measure represented by the hidden Markov model is an essential component of a speech recognition system that follows the statistical pattern recognition approach, and has its root in Bayes's decision theory (Theodoridis and Koutroumbas, 2003). The HMM methodology represented a major step forward from the simple pattern recognition and acoustic-phonetic methods used earlier in automatic speech recognition systems.

The idea of the hidden Markov model appears to have originated in the late 1960s at the Institute for Defense Analyses (IDA) in Princeton, N.J. Len Baum referred to an HMM as a set of probabilistic functions of a Markov chain, which, by definition, involves two nested distributions, one pertaining to the Markov chain and the other to a set of the probability distributions, each associated with a state of the Markov chain, respectively (Baum, 1972). The HMM model attempts to address the characteristics of a probabilistic sequence of observations that may not be a fixed function but instead changes according to a Markov chain. This doubly stochastic process was found to be useful in a number of applications such as stock market prediction and crypto-analysis of a rotary cipher (an encryption device widely used during World War II). Baum's modeling and estimation technique was first shown to work for discrete observations (i.e., ones that assume values from a finite set and thus are governed by discrete probability distributions) and then for random observations that were well modeled using log-concave probability density functions. The technique was powerful but limited. Using a representation theorem by Fan (Liporace, 1982), Liporace, also of IDA, relaxed the log-concave density constraint to include an elliptical symmetric density constraint (thereby including a Gaussian density and a Cauchy density). Baum's doubly stochastic process started to find applications in the speech area, initially in speaker identification systems, in the late 1970s (Poritz, 1982; Liporace, 1982). As more people attempted to use the HMM technique, it became clear that the constraint on the form of the density functions imposed a limitation on the performance of the system, particularly for speaker independent tasks where the speech parameter distribution was not sufficiently well modeled by a simple log-concave or an elliptically symmetric density function. In the early 1980s at Bell Laboratories, the theory of HMM was extended to mixture densities (Juang, 1985; Juang *et al.*, 1986) that have since proven vitally important in ensuring satisfactory recognition accuracy, particularly for speaker independent, large vocabulary speech recognition tasks.

The HMM, being a probability measure, was amenable for incorporation in a larger speech decoding framework which included a language model. The use of a finite-state grammar in large vocabulary continuous speech recognition represented a consistent extension of the Markov chain that the HMM utilized to account for the structure of the language, albeit at a level that accounted for the interaction between articulation and pronunciation. Although these structures (for various levels of the language constraints) were at best crude approximations to the real speech phenomenon, they were computationally efficient and often sufficient to yield reasonable (first-order) performance results. The merger of the hidden Markov model (with its advantage in statistical consistency, particularly in handling acoustic variability) and the finite state network (with its search and computational efficiency, particularly in handling word sequence hypotheses) was an important, although not unexpected, technological development in the mid-1980s.

Figure 7 shows a finite state composite model for the utterance 'show all alerts,' constructed from several context-dependent subword models that represent the corresponding phoneme-like speech units (including a unit for silence [sil] that can occur at the beginning and end of the sentence, as well as at the end of any word in the sentence, as might occur during a pause in speaking). The finite state graph is realized as a Markov chain for calculation of the likelihood, based on the observation sequence (the spectral representation over time) of an unknown utterance. Note that each node in the graph is associated with a probability distribution which accounts for the variability in realizing the corresponding phoneme-like sound. The likelihood that an utterance was generated by the finite state network represented by the model is computed as a sequential sum of local likelihoods related to the elementary units of the composite model. This sequential sum is obtained as a result of optimal state alignment, via a dynamic programming procedure, to maximize the match between the labeled units and the corresponding

"Show all alerts" modeled as phones: ϕ-**sh**-ow, ϕ-**ax**-l, ax-**l**-er, l-**er**-t

Figure 7 A composite finite-state network for the utterance 'show all alerts.'

Figure 8 Multi-layer perceptron.

portions of the speech observations. At any given time, there are a number of hypothesized units whose likelihoods are to be evaluated and the determination of sound identity is based on the maximum likelihood value (or score of the match). The number of hypothesized units for match and that of the paths for search can be at times astronomical and thus may require efficient computational algorithms to solve the problem. A tool called FSM (finite-state machine library), which embodies the above finite state network in a unified transducer framework for incorporation of weighted search was developed in the mid-1990s (Mohri, 1997).

Another technology that was reintroduced in the late 1980s was the idea of artificial neural networks (ANN). Neural networks were first introduced in the 1950s, but failed to produce notable results initially (McCullough and Pitts, 1943). The advent in the 1980s of a parallel distributed processing (PDP) model, which was a dense interconnection of simple computational elements, and a corresponding 'training' method, called error back-propagation, revived interest in the old idea of mimicking the human neural processing mechanism. A particular form of PDP, the multi-layer perceptron, shown in Figure 8, received perhaps the most intense attention then, not because of its analog to neural processing but due to its capability in approximating any function (of the input) to an arbitrary precision, provided no limitation in the complexity of the processing configuration was imposed. If a pattern recognizer is viewed as one that performs a function that maps an input pattern to its class identity, the multi-layer perceptron was then a readily available candidate for this purpose. Early attempts at using neural networks for speech recognition centered on simple tasks like recognizing a few phonemes or a few words (e.g., isolated digits), with good success (Lippmann, 1990). However, as the problem of speech recognition inevitably requires handling of temporal variation, neural networks in their original form have not proven to be extensible to this task. Ongoing research focuses on integrating neural networks with the essential structure of a hidden Markov model to take advantage of its temporal handling capability.

In the 1990s a number of innovations took place in the field of pattern recognition. The problem of pattern recognition, which traditionally followed the framework of Bayes and required estimation of distributions for the data, was transformed into an optimization problem involving minimization of the empirical recognition error (Juang *et al.,* 1997). This fundamental change of paradigm was caused by the recognition of the fact that the distribution functions for the speech signal could not be accurately chosen or defined, and that Bayes' decision theory would become inapplicable under these circumstances. After all, the objective of a recognizer design should be to achieve the least recognition error rather than the best fitting of a distribution function to the given (known) data set as advocated by the Bayes criterion. The concept of minimum classification or empirical error subsequently spawned a number of techniques, among which discriminative training and kernel-based methods such as the support vector machines (SVM) have become popular subjects of study (Juang *et al.,* 1997; Bahl *et al.,* 1986; Vapnik, 1998) and have found applications in speech recognition.

The success of statistical methods revived the interest from (D)ARPA at the juncture of the 1980s and the 1990s, leading to several new speech recognition systems including the Sphinx system from CMU (Lee, 1988), the BYBLOS system from BBN (Schwartz *et al.,* 1989) and the DECIPHER system from Stanford Research Institute (SRI) (Murveit *et al.,* 1989). CMU's Sphinx system successfully integrated the statistical method of hidden Markov models with the network search strength of the earlier Harpy system. Hence, it was able to train and embed context-dependent phone models in a sophisticated lexical decoding network, achieving remarkable results for large-vocabulary continuous speech recognition.

With the support of DARPA, evaluation of speech recognition technology for a wide range of tasks and task vocabularies was diligently pursued throughout the 1990s and into the twenty-first century. Such evaluations were mostly based on the measurement of word (and sentence) error rate as the performance figure of merit of the recognition system. Furthermore, these evaluations were conducted systematically over carefully designed tasks with progressive degrees of difficulty, ranging from the recognition of continuous speech spoken with stylized grammatical structure (as used routinely in military tasks, for example, the Naval Resource Management task); to transcriptions of live (off-the-air) news broadcast, for example, North American Business news, which involves a fairly large vocabulary over 20 000 words;

Figure 9 DARPA benchmark evaluation of speech recognition for a number of tasks.

and conversational speech. Figure 9 shows a chart that summarizes the benchmark performance of various large vocabulary continuous speech recognition tasks, as measured in formal DARPA and National Institute of Standards and Technology (NIST) evaluations (Pallett *et al.*, 1995). In the chart, the task of Resource Management involves a rigidly stylized military expression with a vocabulary of nearly 1000 words. ATIS is a task that involves simple spontaneous speech conversation with an automated air travel information retrieval system; although the speech is spontaneous, its linguistic structure is rather limited in scope. WSJ refers to transcription of a spoken (read) paragraph from the *Wall Street Journal;* the vocabulary size could be as large as 60 000 words. The Switchboard task is one of the most challenging ones proposed by DARPA. The speech is conversational and spontaneous, with many instances of the so-called disfluencies such as partial words, hesitation, and repairs. The general conclusion that can be drawn from these results is that conversational speech, which does not strictly adhere to linguistic constraints, is significantly more difficult to recognize than task-oriented speech that follows strict syntactic and semantic production rules. Also, the evaluation program showed that increasing the amount of speech data used for estimating the recognizer parameters (i.e., the size of the training set) always led to reductions of word error rate. (It is a well-accepted target that in order for virtually any large vocabulary speech recognition task to become viable, the word error rate must fall below a 10% level).

In the 1990s great progress was made in the development of software tools that enabled many individual research programs all over the world. As systems became more sophisticated (many large vocabulary systems now involve tens of thousands of phone unit models and millions of parameters), a well-structured baseline software system became indispensable for further research and development to incorporate new concepts and algorithms. The system that was made available by the Cambridge University team (led by Steve Young), called the Hidden Markov Model Tool Kit (HTK) (Young *et. al.*), was one of the most widely adopted software tools for automatic speech recognition research. Other widely available tool kits for HMM modeling of speech include the Sphinx System from Carnegie-Mellon University. (http://cmusphinx.sourceforge.net/sphinx4/), and the HMM toolkit from Mississippi State University (http://www.isip.msstate.edu/projects/speech/).

Toward a Machine that Communicates

Most speech recognition research, up to the 1980s, considered the major research problem to be one of converting a speech waveform (as an acoustic realization of a linguistic event) into words (as a best-decoded sequence of linguistic units). Many researchers also believed that the speech-to-text process was the necessary first step in the process that enabled a machine to be able to understand and properly respond to human speech. In field evaluations of speech recognition and understanding

technology for a range of tasks, two important things were learned about the speech communication process between humans and machines. First, potential users of a speech recognition system tended to speak natural sentences that often did not fully satisfy the grammatical constraints of the recognizer (e.g., by including out-of-vocabulary [OOV] words, non-grammatical constructs, ill-formed sentences, etc.), and the spoken utterances were also often corrupted by linguistically irrelevant noise components such as ambient noise, extraneous acoustic sounds, interfering speech, etc. Second, as in human-to-human speech communications, speech applications often required a dialog between the user and the machine to reach some desired state of understanding. Such a dialog often required such operations as query and confirmation, thus providing some allowance for speech recognition and understanding errors. The keyword spotting method (and its application in AT&T's Voice Recognition Call Processing (VRCP) System, as mentioned earlier), was introduced in response to the first factor while the second factor focused the attention of the research community on the area of dialog management. Many applications and system demonstrations that recognized the importance of dialog management over a system's raw word recognition accuracy were introduced in the early 1990s with the goal of eventually creating a machine that really mimicked the communicating capabilities of a human. Among these systems, Pegasus and Jupiter developed at the Massachusetts Institute of Technology under Victor Zue were particularly noteworthy demos (Glass and Weinstein, 2001; Zue *et al.*, 2000), and the How May I Help You? (HMIHY©) system at AT&T developed by Allen Gorin was an equally noteworthy service that was introduced as part of AT&T Customer Care for their Consumer Communications Services in 2000 (Gorin *et al.*, 1996).

Pegasus is a speech conversational system that provides information about the status of airline flights over an ordinary telephone line. Jupiter is a similar system with a focus on weather information access, both local and national. These systems epitomized the effectiveness of dialog management. With properly designed dialog management, these systems could guide the user to provide the required information to process a request, among a small and implicit set of menu choices, without explicitly requesting details of the query, e.g., such as by using the dialog management phrase "please say morning, afternoon, or evening" when time frame of the flight was solicited. Dialog management also often incorporated imbedded confirmation of recognized phrases and soft error handling so as to make the user react as if there was a real human agent rather than a machine on the other end of the telephone line. The goal was to design a machine that communicated rather than merely recognized the words in a spoken utterance.

The late 1990s was marked by the deployment of real speech-enabled applications, ranging from AT&T's VRCP (automated handling of operator-assisted calls) and Universal Card Service (customer service line) that were used daily (often by millions of people) in lieu of a conventional voice response system with touch-tone input, to United Airlines' automatic flight information system by SpeechWorks and AT&T's "How May I Help You? (HMIHY)" system for call routing of consumer help line calls. Although automatic speech recognition and speech understanding systems are far from perfect in terms of the word or task accuracy, properly developed applications can still make good use of the existing technology to deliver real value to the customer, as evidenced by the number and extent of such systems that are used on a daily basis by millions of users.

Summary and Outlook

Figure 10 shows a timeline of progress in speech recognition and understanding technology over the past several decades. We see that in the 1960s we were able to recognize small vocabularies (10–100 words) of isolated words, based on simple acoustic-phonetic properties of speech sounds. The key technologies that were developed during this time frame were filter-bank analyses, simple time normalization methods, and the beginnings of sophisticated dynamic programming methodologies. In the 1970s we were able to recognize medium vocabularies (100–1000 words) using simple template-based, pattern recognition methods. The key technologies that were developed during this period were the pattern recognition models, the introduction of LPC methods for spectral representation, the pattern clustering methods for speaker-independent recognizers, and the introduction of dynamic programming methods for solving connected word recognition problems. In the 1980s we started to tackle large vocabulary (1000–unlimited number of words) speech recognition problems based on statistical methods, with a wide range of networks for handling language structures. The key technologies introduced during this period were the hidden Markov model (HMM) and the stochastic language model, which together enabled powerful new methods for handling virtually any continuous speech recognition problem efficiently and with high performance. In the 1990s we were able to build large vocabulary systems with unconstrained language models, and constrained task syntax models for continuous speech recognition and

Figure 10 Milestones in speech recognition and understanding technology over the past 40 years.

understanding. The key technologies developed during this period were the methods for stochastic language understanding, statistical learning of acoustic and language models, and the introduction of finite state transducer framework (and the FSM Library) and the methods for their determination and minimization for efficient implementation of large vocabulary speech understanding systems. Finally, in the last few years, we have seen the introduction of very large vocabulary systems with full semantic models, integrated with text-to-speech (TTS) synthesis systems, and multi-modal inputs (pointing, keyboards, mice, etc.). These systems enable spoken dialog systems with a range of input and output modalities for ease-of-use and flexibility in handling adverse environments where speech might not be as suitable as other input-output modalities. During this period we have seen the emergence of highly natural concatenative speech synthesis systems, the use of machine learning to improve both speech understanding and speech dialogs, and the introduction of mixed-initiative dialog systems to enable user control when necessary.

After nearly five decades of research, speech recognition technologies have finally entered the marketplace, benefiting the users in a variety of ways. Throughout the course of development of such systems, knowledge of speech production and perception was used in establishing the technological foundation for the resulting speech recognizers. Major advances, however, were brought about in the 1960s and 1970s via the introduction of advanced speech representations based on LPC analysis and cepstral analysis methods, and in the 1980s through the introduction of rigorous statistical methods based on hidden Markov models. All of this came about because of significant research contributions from academia, private industry, and the government. As the technology continues to mature, it is clear that many new applications will emerge and become part of our way of life—thereby taking full advantage of machines that are partially able to mimic human speech capabilities.

The challenge of designing a machine that truly functions like an intelligent human is still a major one. Our accomplishments to date are only the beginning and it will take many years before a machine can pass the Turing test, namely, achieving performance that rivals that of a human.

Speech Recognition: Psychology Approaches

What could be simpler than perceiving and recognizing speech? Without any real effort, we identify half a dozen spoken words per second, almost immediately understand the message generated by the sentence they form, and often elaborate appropriate verbal and nonverbal responses before the utterance ends. However, empirical investigation reveals that the perceptual and cognitive mechanisms involved in recognizing speech are far from obvious. The computational complexity that listeners face is experienced first hand by second-language learners and by speech scientists trying to build speech-recognition machines. The problem originates mainly from the nature of the speech signal itself.

Main Properties of the Speech Signal

The fact that speech is conveyed in the auditory modality has dramatic implications for the psychological operations underpinning its recognition. Auditory language processing and written language processing are subjected to such different constraints that the models put forward to account for one or the other overlap only minimally. Over the past 50 years, research in speech recognition has focused on the constraining effects of three main properties of the auditory signal: sequentiality, variability, and continuity.

Sequentiality

One of the most obvious disadvantages of the auditory system compared to the visual system is that the distribution of the auditory information is solely under the speaker's control. From the listener's perspective, the speech signal is transient, and there is no such thing as auditory regressions, in which listeners can replay the words or sentences they just heard. The timing constraints on how speech sounds reach our ears have direct consequences for the time course of speech processing. Because we cannot hold more than a few syllables or words at a time in our auditory short-term memory, word and sentence processing must take place sequentially, in real time. For a large part, listeners are extremely good at keeping up with the rapid flow of speech sounds: Marslen-Wilson (1984) showed that words in sentences are often

Speech Recognition: Psychology Approaches

What could be simpler than perceiving and recognizing speech? Without any real effort, we identify half a dozen spoken words per second, almost immediately understand the message generated by the sentence they form, and often elaborate appropriate verbal and nonverbal responses before the utterance ends. However, empirical investigation reveals that the perceptual and cognitive mechanisms involved in recognizing speech are far from obvious. The computational complexity that listeners face is experienced first hand by second-language learners and by speech scientists trying to build speech-recognition machines. The problem originates mainly from the nature of the speech signal itself.

Main Properties of the Speech Signal

The fact that speech is conveyed in the auditory modality has dramatic implications for the psychological operations underpinning its recognition. Auditory language processing and written language processing are subjected to such different constraints that the models put forward to account for one or the other overlap only minimally. Over the past 50 years, research in speech recognition has focused on the constraining effects of three main properties of the auditory signal: sequentiality, variability, and continuity.

Sequentiality

One of the most obvious disadvantages of the auditory system compared to the visual system is that the distribution of the auditory information is solely under the speaker's control. From the listener's perspective, the speech signal is transient, and there is no such thing as auditory regressions, in which listeners can replay the words or sentences they just heard. The timing constraints on how speech sounds reach our ears have direct consequences for the time course of speech processing. Because we cannot hold more than a few syllables or words at a time in our auditory short-term memory, word and sentence processing must take place sequentially, in real time. For a large part, listeners are extremely good at keeping up with the rapid flow of speech sounds: Marslen-Wilson (1984) showed that words in sentences are often

Figure 1 A waveform of the spoken sentence 'the speech signal is continuous,' with the boundaries between words indicated by vertical lines. Note the absence of any consistent word-boundary cues in the signal. An approximation of the amount of speech that can be held in our acoustic short-term memory is shown in the rectangle.

recognized as early as 200 ms after their onset. However, the sequential nature of speech processing is a feature that many models have struggled to implement, not only because it confronts the modeler with a choice between online (and probabilistic) decision and delayed commitment, but also because the problem is compounded by the lack of clear boundaries between words.

Continuity

The inspection of a speech waveform does not reveal clear correlates to what the human ear perceives as word boundaries (Figure 1). Abrupt drops in sound intensity do not reliably correlate with word boundaries; they often simply indicate syllable boundaries or articulatory gestures involving mouth closure, which are often found in some stop consonants. Yet the absence of boundary markers hardly seems to pose a problem for everyday listening, as the subjective experience of speech is not one of continuity but, rather, of discreteness, i.e., a string of words. The passage from continuity to discreteness constitutes a computational challenge that has usually been referred to as speech segmentation.

Segmentation problems are not limited to finding boundaries between words. At the sublexical level, too, where boundaries between phonemes are blurred by coarticulation, some form of segmentation must occur. Appropriate segmentation between phonemes is important for mapping the signal onto phonemic categories. Likewise, at the sentential level, segmentation between larger units, such as phrases or clauses, allows ideas and concepts to be processed separately. As suggested earlier, segmentation at all levels must be considered within the constraints imposed by the sequential unfolding of the speech input. Thus, by and large, for a speech-recognition model to be viable, segmentation between phonemes, words, and sentential units must be envisaged as an operation taking place online.

Variability

Perhaps the most challenging feature of the speech signal is its high degree of variability. Not even mentioning the differences arising from accented speech, the number of ways in which a word can be pronounced – and hence the resulting number of acoustic stimuli – is virtually infinite. Gender, age, health, mood, speech rate, sentential context, etc., have substantial effects on the articulation of phonemes. Such a degree of variability makes template-based recognition, where each possible instance has its own representation in long-term memory, a very unlikely possibility.

Even more critically, the realization of individual phonemes depends on the phonemes surrounding them. For example, the articulation of the phoneme /d/ in /di/ is surprisingly different from that in /du/. So are the resulting acoustic tokens. This contingency stems primarily from the biomechanical constraints imposed by the shape and muscular arrangement of the vocal tract forcing a speaker to coarticulate phonemes, that is, to overlap the articulation of one phoneme with that of the phonemes around it. Coarticulation is easily experienced when saying *see* or *sue*, in which the articulatory movements pertaining to the vowel can be felt (and seen) even before the onset of the consonant. The lack of a clear mapping between portions of the acoustic signal and individual phonemes has often been referred to as the lack of invariance problem. Although sometimes used in speech machine recognition, individual representations for all possible phoneme successions (e.g., all possible diphones) constitute a rather uneconomical

Figure 2 Schematic spectrogram for the syllables /di/ and /du/. Note the acoustic dissimilarity between the second formant transition of /di/ and that of /du/. Yet the onset of the two syllables is perceived as /d/.

way of dealing with phoneme variability. However, as will be described later, none of the alternative solutions proposed by psycholinguists so far have proved entirely satisfying either (Figure 2).

Modeling the Psychology of Speech Recognition

The three features of the speech signal reviewed above provide a constraining ground for psychological theories of speech recognition. Because of the degree of complexity in modeling speech recognition as a whole, from phoneme perception to sentence understanding, models have often confined their investigation to one of three processing levels: sublexical, lexical, and sentential. Below, we follow the same structure.

Speech Perception (Sublexical Units)

From Variable Acoustics to Discrete Phonemes The lack of simple one-to-one mapping rules between the physical signal and phonemes (about 40 in English) amounts to a problem of perceptual constancy: how can a listener match an infinity of acoustic exemplars with one and only one among 40 phonemes? A first possibility is that each phoneme is recognized as a unique combination of phonetic features, and each phonetic feature is acoustically invariant. For example, each of the phonetic features making up the phoneme /b/ (stop, voiced, bilabial) would have a relatively constant acoustic signature across exemplars. A configuration of phonetic-feature detectors, possibly specified at the neural level, would then maximally respond to that particular phoneme and lead to its identification. Although attractive, this conceptualization fails to account for the fact that acoustic events suffer from the variability problem to some extent too since, as illustrated earlier, a stop burst can be interpreted as /p/ or /k/ depending on the following vowel.

Another possibility is that listeners categorize the speech input into discrete phonemes not so much because they have mapping rules about how to perceive them but because they know how to produce them. The motor theory, devised by Liberman *et al.* (1967), posits that speech sounds are perceived by reference to the articulatory gestures used to produce them. Here, an acoustic event (e.g., the burst from the above example) is correctly mapped onto a particular phonetic feature (e.g., bilabial) because the listener implicitly knows which auditory stimulus typically results from the articulation of which event. The motor theory can help explain how listeners deal with some acoustic-variability problems and it provides a satisfactory account of a number of perceptual phenomena. For instance, the categorical perception of stop consonants – e.g., the perception of an acoustic continuum ranging smoothly from /p/ to /k/ as either a clear /p/ or a clear /k/ – would result from the knowledge of the typical articulatory gestures involved in uttering the sounds (Figure 3). However, the motor theory suffers from a number of weaknesses. First, the link between phonemes and articulatory gestures turns out to be just as variable as that between phonemes and the acoustic signal. Thus, as such, the motor theory cannot fully solve the lack-of-invariance problem. Second, some perceptual phenomena (e.g., categorical perception) that were initially attributed to a link to production have been found in populations lacking the production component, such as nonhuman primates and young infants. Finally, as elegant as it appeared, the theory

Figure 3 Schematic patterns of identification (left) and discrimination (right) for categorical perception (top two panels) and continuous perception (bottom two panels). When an auditory continuum (e.g., from /b/ to /k/) is perceived categorically, the listener experiences a sharp perceptual boundary between categories and finer discrimination around the boundary than inside the categories. When a continuum (e.g., from /ɪ/ to /æ/) is perceived continuously, identification functions mimic the smooth physical changes in the stimulus and discrimination is roughly the same along the entire continuum.

Figure 4 Illustrations of two approaches to phoneme perception. (A) Phoneme perception is influenced by top-down connections from the lexical level, e.g., McClelland and Elman (1986) and Samuel (1997). (B) Phoneme perception is assisted but not modified by lexical knowledge, e.g., Norris *et al.* (2000). R represents the level at which the phoneme-perception response is generated.

never managed to fully specify the nature of the perception–production link that was at its core and the nature of the stored motor patterns.

Subsequent theories have downplayed the direct link to the production component, but not necessarily the reference to articulatory gestures. Fowler (1986), for instance, suggested that the articulatory gestures corresponding to specific phonemes can be recovered from the speech signal itself. This position, which is based on the assumption that the speech input is much richer and informative than previously thought, offers a more ecological approach than the motor theory because it places an emphasis on the signal rather than abstract mental representations. Since the original formulation of the motor theory, both production-based and auditory theories of speech perception have been proposed, but none so far has produced a fully satisfactory account of how the perceptual system solves the invariance problem.

Bottom-up and Top-down Information Flows The search for perceptual mechanisms able to extract invariant representations from a variable signal can be substantially facilitated (bypassed?) if we consider the proximal context in which phonemes usually occur, namely, words. In this view, the analysis of the signal, whether it is based on acoustic, phonetic, or articulatory processing, is supplemented by top-down lexical knowledge. Collaboration between bottom-up and top-down processes not only reduces the acoustic variability problem, it also allows acoustically degraded phonemes to be identified. For example, a phoneme (e.g., /s/ in *cigarette*) could be recognized even if mispronounced (e.g., /ʃ/) because of the constraining lexical context in which it is heard (Figure 4).

While the contribution of lexical knowledge to speech processing is undeniable, it is unclear whether lexical knowledge truly affects perception (creating auditory illusions) or simply produces a postperceptual bias (i.e., a preference for what ought to be

heard, i.e., a known word). Following the observation that a lexical context can produce powerful phoneme illusions, Samuel (1997) contends that phonemic processing has both bottom-up and top-down components. In contrast, in their MERGE model, Norris *et al.* (2000) appeal to both logic and computer simulations to show that efficient speech perception can be achieved without top-down connections, and do so at a lower computational cost. While both sides of the debate have had countless supporters and detractors, the true remaining ground to win seems to be about not only a definition of what constitutes perception (the actual boundary between bottom and top), but also an account of the time-course of bottom-up and top-down effects. Norris' group, for instance, claims that, while lexical feedback does not alter speech perception during online tasks, it does so over longer periods of time, e.g., in the course of word and sound learning.

Is Speech Perceived as a String of Units? Describing the speech input as a sequence of phonemes might be convenient for modelers, but not everyone agrees that phonemes are perceptually relevant in speech recognition. As noted before, acoustic variability casts serious doubts on the perceptual reality of phonemes. Phonetic features and articulatory gestures have been described as important building blocks in speech perception as well, but they too have proved somewhat unsatisfactory. The search for perceptual units is important because it ultimately allows one to specify a finite number of sublexical units serving as intermediary representations between the signal and lexical representations.

Perhaps the most popular alternative to phonemes and subphonemic features is the syllable. Being articulatorily relatively stable, syllables do not suffer from acoustic variability as much as phonemes. Savin and Bever (1970), for example, found that listeners were faster at detecting syllable targets than their initial phonemes, suggesting that syllables are primary perceptual units while phonemes are derived from them. Moreover, syllables are psychologically more intuitive to listeners than phonemes because of their contribution to the rhythmic nature of speech. In this respect, languages with an essentially syllabic rhythmic structure, such as French, are particularly good candidates for syllabic perception. The role of syllables in the perception of non-syllable-timed languages is less clear. The perception of languages based on a alternation between strong and weak syllables, such as English and Dutch, seems to involve a combination of syllabic information and prosodic cues. Japanese listeners, on the other hand, appear to exploit the moraic rhythm of their language (morae are units whose structure and size are intermediate between those of syllables and phonemes).

Nowadays, evidence for not only phonemes, syllables, and morae, but also for disyllables and feet is pitted against the possibility that perceptual units are simply emergent properties of the interaction between bottom-up and top-down knowledge (Goldinger and Azuma, 2003). While the intensive research on the units of speech perception has not yet yielded a consensus, it has at least generated important questions for future investigation:

1. Is there one or several perceptual units?
2. Are these units universal or language-specific?
3. If units are language specific, is their involvement dictated by the language we hear or the language we speak?
4. What role do perceptual units have in lexical access?

Spoken-Word Recognition

Early research in speech perception had a clear bottom-up agenda, in that it focused almost entirely on the mapping between the signal and sublexical units. This approach was legitimately motivated by the observation that listeners are very good at categorizing phonemes in the absence of any lexical or contextual information. Subsequent research attempted to bridge speech perception and spoken-word recognition around the notion of sublexical units. If there are such things as sublexical or perceptual units, how do they contribute to lexical access? This question, in turn, drew attention to issues of architectural structure, lexical representations, and flow of information.

Intermediate Representations The ultimate consequence of lexical access is the activation of a unique word representation stored in long-term memory, making available not only its phonological content but also its meaning. Models that do not postulate intermediate representations between the signal and lexical representations have often done so at the cost of great redundancy in the lexicon or out of computational simplicity or (e.g., the Logogen model, Morton, 1969). Most likely, some form of intermediate representations mediates the signal and the lexicon. As mentioned earlier, the most likely candidates so far have been the phoneme and the syllable. Most models, either by default or by choice, have included a phoneme layer in their mapping algorithm. While phonemes suffer from acoustic variability, a great deal of empirical evidence supports their involvement at some level of processing. For example, recognition performance can be predicted from phoneme-based

estimates of a word's lexical neighborhood – the number of similar-sounding words differing from the target word by one phoneme (e.g., the Neighborhood Activation Model, NAM, Luce and Pisoni, 1998). However, the effects attributed to a phoneme layer can often also be accounted for by smaller units, such as phonetic features, or even from competition within the lexicon. As an alternative, syllables have the advantage of providing a more parsimonious approach to lexical activation. Indeed, initiating lexical access on every syllable rather than every phoneme reduces the amount of spurious lexical activity considerably. This benefit is particularly important when the words appear in connected speech, as will be discussed later. A problem with the syllabic-parsing approach, however, is that the concept of syllabary (i.e., a putative memory store of all common syllables in the language), which it often implies, has not received strong empirical support (Figure 5).

Although the evidence for intermediate representations, on the whole, far outweighs the evidence against them, the nature, number, and contingencies of such intermediate units are still subject to debate. The possibility that intermediate units and perceptual units are one and the same thing is also being considered. Interestingly, this would imply that input-to-lexicon mapping mechanisms could very well differ from one language to another, with languages featuring large intermediate units being computationally more efficient than languages relying on smaller units.

Lexical Activation and Competition Both intuitively and empirically, spoken-word recognition appears to be about discriminating an uttered word from other words held in long-term memory. Models have formalized this discrimination process by emphasizing two key notions: activation and competition. Activation is thought to be an early processing stage whereby lexical entries mapping the unfolding input are activated – independent of whether or not this process is mediated by intermediate units. Competition between activated lexical entries is then essentially a pruning mechanism whose result is to isolate a single candidate for recognition.

Activation itself can be more or less constrained. For instance, the Cohort model (Marlen-Wilson, 1987) and the Metrical Segmentation Strategy (MSS, Cutler and Norris, 1988) restrict activation to particular locations in the speech stream, such as words' onsets (if known) or strong syllables. In these models, upon hearing the word *temper*, words like *taste*, *terror*, *temporal*, etc. would be briefly activated, but not words like *potential* or *percent*, because these overlap later portions (Cohort) or start with a weak syllable (MSS). In contrast, TRACE (McClelland and Elman, 1986) and Shortlist (Norris, 1994) allow any portion of the input to activate lexical representations. Thus, in the above example, even late-occurring fragments would result in some activation. While the latter solution might seem computationally less economical, it does not have to postulate separate segmentation mechanisms to locate word boundaries, as these are naturally identified as a result of the activation/selection process.

Figure 5 Examples of favorable and unfavorable lexical neighborhoods. A word in a favorable neighborhood (e.g., *print*) is recognized easily because it has few similar-sounding neighbors and these are relatively low frequency – frequency is schematically represented by the font size. A word in an unfavorable neighborhood (e.g., *grip*) is recognized less easily because it has many similar-sounding neighbors and some of them are relatively high frequency.

In all models, however, a large number of nontarget candidates are activated in the initial mapping stage. An important question arises as to whether the deactivation of such candidates is a passive consequence of an increasingly accurate match between the unfolding input and the lexicon, or the result of a more active competition process between activated candidates. Mutual inhibition between lexical candidates, which is often referred to as lateral inhibition, is only found in TRACE and Shortlist, in which entries tightly fitting the input not only get activated most, but also reduce the activation of entries with a less good fit. Selection in Cohort and NAM is a more input-driven affair, with the activity of nontarget words passively decaying as their fit with the signal diminishes. However, NAM imposes a form of lexical penalty to word candidates belonging to a densely populated area of the lexicon: words with many similar-sounding and high-frequency neighbors are recognized more slowly than words in a sparser neighborhood. A later instantiation of NAM, called PARSYN (short for Paradigmatic and Syntagmatic, Luce *et al.*, 2000), has more fully formalized such competition effects by including lateral inhibition between lexical neighbors. In fact, PARSYN pushes the inhibitory architecture one step further by assuming inhibition not only within the lexicon but also between the lexicon and sublexical units.

Although quite different in their architecture and processes, the above models have evolved in

complexity over the years in an attempt to account for a growing list of perceptual and cognitive phenomena related to speech processing. While they may have lost some testability in the process, they have contributed to our understanding of how spoken-word recognition is molded by both the acoustic signal and the listener's lexical knowledge and expectations.

Fluent Speech and Sentence Comprehension

Phonemes and words are rarely heard in isolation. They usually constitute the building blocks of sentences, which are themselves often heard in richly contexualized conversations. The impact of sentential and contextual information on word and phoneme recognition has been demonstrated on several occasions. For instance, while the intelligibility of the words making up a sentence is high – or at least appears so – when the sentence is played in its entirety, it drops dramatically when the words are excised from the sentence and played in isolation. Similarly, when an acoustically degraded phoneme renders a word ambiguous (**eel*, where the asterisk denotes the degraded phoneme), the sentential context usually takes over. In this example, *wheel* is heard more often than *peel* in *It was found that the *eel was on the axle* and vice versa in *It was found that the *eel was on the orange* (Warren and Warren, 1970). The intervention of higher-order knowledge is also manifest when a segmentation problem occurs. Listeners are likely to hear *straight issue* rather than *stray tissue* at the end of the sentence *How much we should pay for health care is not a* ... and the opposite at the end of *The detectives realized that the discarded scarf was not a* ... These phenomena, of course, must be analyzed in the context of the transient nature of the signal, which, as we saw earlier, imposes severe constraints on processing the time course.

Segmenting Words from Fluent Speech The acoustic signal of a typical sample of conversational speech contains few noticeable interruptions, and these are far less reliable indicators of word boundaries than are blank spaces in the written language. While the continuous nature of speech hardly seems to pose a problem for everyday listening, it constitutes a challenge to speech scientists. Speech segmentation has traditionally been tackled from two standpoints. According to one, important cues to word boundaries can be found in the signal itself. While many of these are acoustic (e.g., silent pauses, intonation contour, allophonic specificity), others are based on statistical regularities. For example, phonemes that are rarely found next to each other in the words of a language (e.g., /fh/) tend to be perceived as word boundaries when heard in connected speech (e.g., *tough hero*). Because such regularities often depend on the phonological structure of a particular language, the cues used in the segmentation of one language might not be the same as those used in the segmentation of another language.

An alternative approach to speech segmentation gives lexical knowledge and contextual information a critical role in determining likely word boundaries. Here, lexical candidates activated in multiple locations in the speech signal compete for a parsing solution that does not leave any fragments lexically unaccounted for (e.g., *great wall* is favored over *gray twall*, because *twall* in not an English word). For utterances in which lexical information cannot provide proper disambiguation, semantic, syntactic, and pragmatic expectations can sometimes compensate (cf. the *straight issue* vs. *stray tissue* example in the previous section) (**Figure 6**).

Since there is compelling evidence that both types of segmentation mechanisms contribute to segmentation, the debate has shifted from finding **which** segmentation cues are available to describing **how** sublexical, lexical, and contextual sources of information interact when present in combination. For instance, when sublexical cues conflict with contextual expectations (e.g., *stray tissue* being pronounced as *straight issue* in a context favoring the former), is there by-default reliance on higher-level information? The problem is made even more complex by the fact that the time of arrival of some of these cues can stretch over the entire length of an utterance (e.g., sentential context), whereas that of others is confined to a phoneme or two (e.g., allophony, phonotactics).

Although fluctuations in lexical activity during speech segmentation have been extremely hard to measure experimentally, powerful online tools have recently started to become available. Electrophysiological devices, for example, are capable of tracking important changes in brain activity over the course of a spoken sentence (see Van Petten, 1995, for a summary of early findings). Eye-tracking procedures, too, have allowed progress to be made in modeling the time-course of speech recognition. By monitoring a participant's eye movements over a visual display while he or she is hearing spoken instructions (e.g., *Move the red square under the blue circle*), it is possible to determine how fast word recognition happens. Because it bypasses any motor commands associated with manual responses (e.g., button push), eye-tracking allows considerably more accurate time resolution than other behavioral methods (e.g., phoneme monitoring, word spotting, lexical decision). Using eye-tracking, Allopenna *et al.* (1998) showed that, upon hearing a spoken word (e.g., *beaker*),

Syntactic expectations
- The children /lʌv#sparks/ (love sparks)
- The child /lʌvs#parks/ (loves parks)

Semantic inferences
- How much we should pay for health care is not a /streɪt#ɪʃu/ (straight issue)
- The detectives realized that the discarded scarf was not a /streɪ#tɪʃ/ (stray tissue)

Lexical knowledge
- /greɪt#wɔl/ (great wall)
- */greɪ#twɔl/ (gray twall)

Probabilistic phonotactics
- /koref#hɪst/, with /fh/ having low within-word frequency
- */korefh#ɪst/

Lexical stress
- /ɪn#'tenʃən/ (in tension), where strong syllables are treated as word initial
- */#ɪn'tenʃən/ (intention)

Allophony
- /teɪks#p^{h}eərs/ (takes pears), with /p/ aspirated
- /teɪk#speərs/ (take spares), with /p/ unaspirated

Figure 6 Types of information that listeners can use to segment words from fluent speech. In conversational settings, these sources of information are found in combination and often converge. Asterisks represent unlikely segmentation solutions given a particular type of cue.

listeners temporarily activated not only words that shared the onset of the test word (e.g., *beetle*) but also words that shared its rhyme (e.g., *speaker*). The relative time-course of the two sets of competitors differed, however. The target word and the onset competitor were fixated to an equal extent as early as 200 ms after the onset of the target, with fixations to the onset competitor dropping around 400 ms onward. Fixations to the rhyme competitor were observed between 300 and 800 ms. These findings are critical not only because they demonstrate that lexical access closely shadows the unfolding of the speech signal but also because they provide strong empirical evidence that multiple and overlapping candidates are considered simultaneously during speech processing and segmentation (Figure 7).

Syntactic Parsing Phoneme categorization, word segmentation, and lexical access are only the necessary steps before an utterance can be understood. A critical stage linking word recognition to sentence comprehension is called syntactic parsing, that is, the assignment of the words of a sentence to their respective syntactic category (noun, verb, adverb, etc.) and the clustering of these words into phrases and clauses (the syntactic tree). The importance of assigning words to their correct syntactic categories is often unintentionally illustrated in newspaper headlines, i.e., *Police seek orange attackers*, whose meaning can be quite different if *orange* is treated as a noun or an adjective (Harley, 2001). The structuring of words into phrases and clauses is even more crucial because it involves making decisions over much longer stretches of a sentence. For instance, in *When Jane eats food gets thrown*, *food* tends to be treated by default as the object of *eats* rather than the subject of *gets*. In the context of the sentence, this interpretation is incorrect, hence leading the listener astray, or 'up the garden path' as it is commonly referred to. Parsing must be undone and attempted again, following a different syntactic tree this time.

Two major questions about syntactic parsing arise. First, what is the time-course of syntactic parsing? Do listeners assign words to syntactic categories and to phrases as they hear them or do they leave their options open and wait until the end of the sentence to commit to a particular parsing? Second, is parsing a solely syntactic process, driven by rules of grammar, or does it allow contextual information to influence the online construction of the syntactic tree? In the garden path model (Frazier, 1987), the initial parsing of an incoming sentence is exclusively and autonomously driven by syntactic principles, with little regard for contextual or thematic information. In most situations, this first stage is sufficient. However, when this initial parsing results in interpretative ambiguities or contradictions with the context, it needs to be revised to integrate nonsyntactic information. The primacy of syntactic rules has been illustrated in a number of eye-tracking experiments conducted with written materials. For instance, fixation durations are longer and eye movements more complex in a sentence like *I know Peter left* than in *I know Peter well* because a syntactic principle called minimal attachment, which aims for syntactic simplicity, dictates that *Peter* should be treated as the object of the main verb *know*, not the subject of another clause. Thus, the disrupted eye movements suggest that the

Figure 7 Probability of fixating various items in a visual display while hearing *Pick up the beaker*. Note the temporary activation of the item sharing its initial portion with the referent (*beetle*) and of that sharing its rhyme (*speaker*). The raft floated down the river sank.
I convinced her children are noisy.

Figure 8 Examples of garden-path sentences.

initial stage of parsing is purely syntactic and integration with the rest of the sentence takes place in a subsequent, corrective stage (Figure 8).

This autonomous and serial approach to parsing is often pitted against constraint-satisfaction models, which advocate interactive and parallel parsing operations (e.g., Trueswell and Tanenhaus, 1994). Here, lexical, semantic, and pragmatic information is thought to contribute, online, to the selection of the most appropriate syntactic construction – the one offering the best fit given syntactic and nonsyntactic constraints. The critical aspect on which these models differ from autonomous views pertains to the nature of the minimal-attachment principle. For constraint-satisfaction models, a syntactic parse following the minimal-attachment principle is only one among several constructions under consideration. In fact, strong contextual information may very well cause the language user to bypass syntactic preferences altogether. Tanenhaus *et al.* (1995) showed this convincingly by monitoring participants' eye movements over a visual display while they heard the sentence *Put the apple on the towel in the box*. An autonomous approach to parsing predicts that, regardless of the visual context, *on the towel* should always be interpreted as the destination of the verb phrase – at least initially – because this construction is syntactically simpler. However, eye-movement trajectories revealed that this was the case only if the visual display did not provide cues for the alternative construction, i.e., one in which *on the towel* is the location of the object to be picked up rather than its destination. When the visual display made the syntactically simpler construction unlikely, listeners adjusted their gaze accordingly. Thus, syntactic parsing appears to be a fully interactive process that integrates various sources of information online.

Conclusion

Research on the perceptual and cognitive aspects of speech recognition has progressed substantially in the past 20 years. Owing to more sophisticated and flexible models, together with new experimental techniques, our understanding of how listeners handle the properties of the speech signal mentioned at the beginning of this chapter (sequentiality, continuity, and variability) has become more complete and, hopefully, more accurate. In the process, however, it has also become evident that answers to some questions can only be gained cross-disciplinarily. Connectionist approaches to speech recognition have already demonstrated the benefit of integrating cognitive psychology with informatics and neurosciences. Likewise, a description of the speech signal and the syntactic complexity of its higher-order representation can only profit from cross-talks with the acoustic and linguistic sciences. The increasingly common integration of behavioral techniques and neuroimaging is an encouraging illustration of this trend.

a dialog between a person and a machine) and the response to that utterance from the machine. Figure 1 shows such a sequence of events, which is often referred to as the speech dialog circle, using an example in the telecommunications context.

The customer initially makes a request by speaking an utterance that is sent to a machine, which attempts to recognize, on a word-by-word basis, the spoken speech. The process of recognizing the words in the speech is called automatic speech recognition (ASR) and its output is an orthographic representation of the recognized spoken input. The ASR process will be discussed in the next section. Next the spoken words are analyzed by a spoken language understanding (SLU) module, which attempts to attribute meaning to the spoken words. The meaning that is attributed is in the context of the task being handled by the speech dialog system. (What is described here is traditionally referred to as a limited domain understanding system or application.) Once meaning has been determined, the dialog management (DM) module examines the state of the dialog according to a prescribed operational workflow and determines the course of action that would be most appropriate to take. The action may be as simple as a request for further information or confirmation of an action that is taken. Thus if there were confusion as to how best to proceed, a text query would be generated by the spoken language generation module to hopefully clarify the meaning and help determine what to do next. The query text is then sent to the final module, the text-to-speech synthesis (TTS) module, and then converted into intelligible and highly natural speech, which is sent to the customer who decides what to say next based on what action was taken, or based on previous dialogs with the machine. All of the modules in the speech dialog circle can be 'data-driven' in both the learning and active use phases, as indicated by the central Data block in Figure 1.

A typical task scenario, e.g., booking an airline reservation, requires navigating the speech dialog circle many times – each time being referred to as one 'turn' – to complete a transaction. (The average number of turns a machine takes to complete a prescribed task is a measure of the effectiveness of the machine in many applications.) Hopefully, each time through the dialog circle enables the customer to get closer to the desired action either via proper understanding of the spoken request or via a series of clarification steps. The speech dialog circle is a powerful concept in modern speech recognition and understanding systems, and is at the heart of most speech understanding systems that are in use today.

Basic ASR Formulation

The goal of an ASR system is to accurately and efficiently convert a speech signal into a text message transcription of the spoken words, independent of the device used to record the speech (i.e., the

Figure 1 The conventional speech dialog circle.

transducer or microphone), the speaker, or the environment. A simple model of the speech generation process, as used to convey a speaker's intention is shown in Figure 2.

It is assumed that the speaker decides what to say and then embeds the concept in a sentence, W, which is a sequence of words (possibly with pauses and other acoustic events such as uh's, um's, er's, etc.). The speech production mechanisms then produce a speech waveform, $s(n)$, which embodies the words of W as well as the extraneous sounds and pauses in the spoken input. A conventional automatic speech recognizer attempts to decode the speech, $s(n)$, into the best estimate of the sentence, $\hat{W}$, using a two-step process, as shown in Figure 3.

The first step in the process is to convert the speech signal, $s(n)$, into a sequence of spectral feature vectors, X, where the feature vectors are measured every 10 ms (or so) throughout the duration of the speech signal. The second step in the process is to use a syntactic decoder to generate every possible valid sentence (as a sequence of orthographic representations) in the task language, and to evaluate the score (i.e., the *a posteriori* probability of the word string given the realized acoustic signal as measured by the feature vector) for each such string, choosing as the recognized string, $\hat{W}$, the one with the highest score. This is the so-called maximum *a posteriori* probability (MAP) decision principle, originally suggested by Bayes. Additional linguistic processing can be done to try to determine side information about the speaker, such as the speaker's intention, as indicated in Figure 3.

Mathematically, we seek to find the string $\hat{W}$ that maximizes the *a posteriori* probability of that string, when given the measured feature vector X, i.e.,

$$\hat{W} = \arg\max_{W} P(W|X)$$

Using Bayes Law, we can rewrite this expression as:

$$\hat{W} = \arg\max_{W} \frac{P(X|W)P(W)}{P(X)}$$

Thus, calculation of the *a posteriori* probability is decomposed into two main components, one that defines the *a priori* probability of a word sequence W, $P(W)$, and the other the likelihood of the word string W in producing the measured feature vector, $P(X|W)$. (We disregard the denominator term, $P(X)$, since it is independent of the unknown W). The latter is referred to as the acoustic model, $P_A(X|W)$, and the former the language model, $P_L(W)$ (Rabiner *et al.*, 1996; Gauvain and Lamel, 2003). We note that these quantities are not given directly, but instead are usually estimated or inferred from a set of training data that have been labeled by a knowledge source, i.e., a human expert. The decoding equation is then rewritten as:

$$\hat{W} = \arg\max_{W} P_A(X|W)P_L(W)$$

We explicitly write the sequence of feature vectors (the acoustic observations) as:

$$X = \mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_N$$

where the speech signal duration is N frames (or N times 10 ms when the frame shift is 10 ms). Similarly, we explicitly write the optimally decoded word sequence as:

$$\hat{W} = w_1 w_2 \ldots w_M$$

where there are M words in the decoded string. The above decoding equation defines the fundamental statistical approach to the problem of automatic speech recognition.

It can be seen that there are three steps to the basic ASR formulation, namely:

- Step 1: acoustic modeling for assigning probabilities to acoustic (spectral) realizations of a sequence

Figure 2 Model of spoken speech.

Figure 3 ASR decoder from speech to sentence.

of words. For this step we use a statistical model (called the hidden Markov model or HMM) of the acoustic signals of either individual words or subword units (e.g., phonemes) to compute the quantity $P_A(X|W)$. We train the acoustic models from a training set of speech utterances, which have been appropriately labeled to establish the statistical relationship between X and W.

- Step 2: language modeling for assigning probabilities, $P_L(W)$, to sequences of words that form valid sentences in the language and are consistent with the recognition task being performed. We train such language models from generic text sequences, or from transcriptions of task-specific dialogues. (Note that a deterministic grammar, as is used in many simple tasks, can be considered a degenerate form of a statistical language model. The 'coverage' of a deterministic grammar is the set of permissible word sequences, i.e., expressions that are deemed legitimate.)
- Step 3: hypothesis search whereby we find the word sequence with the maximum *a posteriori* probability by searching through all possible word sequences in the language.

In step 1, acoustic modeling (Young, 1996; Rabiner *et al.*, 1986), we train a set of acoustic models for the words or sounds of the language by learning the statistics of the acoustic features, X, for each word or sound, from a speech training set, where we compute the variability of the acoustic features during the production of the words or sounds, as represented by the models. For large vocabulary tasks, it is impractical to create a separate acoustic model for every possible word in the language since it requires far too much training data to measure the variability in every possible context. Instead, we train a set of about 50 acoustic-phonetic subword models for the approximately 50 phonemes in the English language, and construct a model for a word by concatenating (stringing together sequentially) the models for the constituent subword sounds in the word, as defined in a word lexicon or dictionary, where multiple pronunciations are allowed). Similarly, we build sentences (sequences of words) by concatenating word models. Since the actual pronunciation of a phoneme may be influenced by neighboring phonemes (those occurring before and after the phoneme), the set of so-called context-dependent phoneme models are often used as the speech models, as long as sufficient data are collected for proper training of these models.

In step 2, the language model (Jelinek, 1997; Rosenfeld, 2000) describes the probability of a sequence of words that form a valid sentence in the task language. A simple statistical method works well, based on a Markovian assumption, namely that the probability of a word in a sentence is conditioned on **only** the previous N–1 words, namely an N-gram language model, of the form:

$$P_L(W) = P_L(w_1, w_2, \ldots, w_M) = \prod_{m=1}^{M} P_L(w_m | w_{m-1}, w_{m-2}, \ldots, w_{m-N+1})$$

where $P_L(w_m|w_{m-1}, w_{m-2}, \ldots, w_{m-N+1})$ is estimated by simply counting up the relative frequencies of N-tuples in a large corpus of text.

In step 3, the search problem (Ney, 1984; Paul, 2001) is one of searching the space of all valid sound sequences, conditioned on the word grammar, the language syntax, and the task constraints, to find the word sequence with the maximum likelihood. The size of the search space can be astronomically large and take inordinate amounts of computing power to solve by heuristic methods. The use of methods from the field of Finite State Automata Theory provide finite state networks (FSNs) (Mohri, 1997), along with the associated search policy based on dynamic programming, that reduce the computational burden by orders of magnitude, thereby enabling exact solutions in computationally feasible times, for large speech recognition problems.

Development of a Speech Recognition System for a Task or an Application

Before going into more detail on the various aspects of the process of automatic speech recognition by machine, we review the three steps that must occur in order to define, train, and build an ASR system (Juang *et al.*, 1995; Kam and Helander, 1997). These steps are the following:

- Step 1: choose the recognition task. Specify the word vocabulary for the task, the set of units that will be modeled by the acoustic models (e.g., whole words, phonemes, etc.), the word pronunciation lexicon (or dictionary) that describes the variations in word pronunciation, the task syntax (grammar), and the task semantics. By way of example, for a simple speech recognition system capable of recognizing a spoken credit card number using isolated digits (i.e., single digits spoken one at a time), the sounds to be recognized are either whole words or the set of subword units that appear in the digits /zero/ to /nine/ plus the word /oh/. The word vocabulary is the set of 11 digits. The task syntax allows any single digit to be spoken, and the task

Figure 4 Framework of ASR system.

semantics specify that a sequence of isolated digits must form a valid credit card code for identifying the user.

- Step 2: train the models. Create a method for building acoustic word models (or subword models) from a labeled speech training data set of multiple occurrences of each of the vocabulary words by one or more speakers. We also must use a text training data set to create a word lexicon (dictionary) describing the ways that each word can be pronounced (assuming we are using subword units to characterize individual words), a word grammar (or language model) that describes how words are concatenated to form valid sentences (i.e., credit card numbers), and finally a task grammar that describes which valid word strings are meaningful in the task application (e.g., valid credit card numbers).
- Step 3: evaluate recognizer performance. We need to determine the word error rate and the task error rate for the recognizer on the desired task. For an isolated digit recognition task, the word error rate is just the isolated digit error rate, whereas the task error rate would be the number of credit card errors that lead to misidentification of the user. Evaluation of the recognizer performance often includes an analysis of the types of recognition errors made by the system. This analysis can lead to revision of the task in a number of ways, ranging from changing the vocabulary words or the grammar (i.e., to eliminate highly confusable words) to the use of word spotting, as opposed to word transcription. As an example, in limited vocabulary applications, if the recognizer encounters frequent confusions between words like 'freight' and 'flight,' it may be advisable to change 'freight' to 'cargo' to maximize its distinction from 'flight.' Revision of the task grammar often becomes necessary if the recognizer experiences substantial amounts of what is called 'out of grammar' (OOG) utterances, namely the use of words and phrases that are not directly included in the task vocabulary (ISCA, 2001).

The Speech Recognition Process

In this section, we provide some technical aspects of a typical speech recognition system. Figure 4 shows a block diagram of a speech recognizer that follows the Bayesian framework discussed above.

The recognizer consists of three processing steps, namely feature analysis, pattern matching, and confidence scoring, along with three trained databases, the set of acoustic models, the word lexicon, and the language model. In this section, we briefly describe each of the processing steps and each of the trained model databases.

Feature Analysis

The goal of feature analysis is to extract a set of salient features that characterize the spectral properties of the various speech sounds (the subword units) and that can be efficiently measured. The 'standard' feature set for speech recognition is a set of mel-frequency cepstral coefficients (MFCCs) (which perceptually match some of the characteristics of the spectral analysis done in the human auditory system) (Davis and Mermelstein, 1980), along with the first- and second-order derivatives of these features. Typically about 13 MFCCs and their first and second derivatives (Furai, 1981) are calculated every 10 ms, leading to a spectral vector with 39 coefficients every 10 ms. A block diagram of a typical feature analysis process is shown in Figure 5.

The speech signal is sampled and quantized, pre-emphasized by a first-order (highpass) digital filter with pre-emphasis factor α (to reduce the influence of glottal coupling and lip radiation on the estimated

Figure 5 Block diagram of feature analysis computation.

vocal tract characteristics), segmented into frames, windowed, and then a spectral analysis is performed using a fast Fourier transform (FFT) (Rabiner and Gold, 1975) or linear predictive coding (LPC) method (Atal and Hanauer, 1971; Markel and Gray, 1976). The frequency conversion from a linear frequency scale to a mel frequency scale is performed in the filtering block, followed by cepstral analysis yielding the MFCCs (Davis and Mermelstein, 1980), equalization to remove any bias and to normalize the cepstral coefficients (Rahim and Juang, 1996), and finally the computation of first- and second-order (via temporal derivative) MFCCs is made, completing the feature extraction process.

Acoustic Models

The goal of acoustic modeling is to characterize the statistical variability of the feature set determined above for each of the basic sounds (or words) of the language. Acoustic modeling uses probability measures to characterize sound realization using statistical models. A statistical method, known as the hidden Markov model (HMM) (Levinson *et al.*, 1983; Ferguson, 1980; Rabiner, 1989; Rabiner and Juang, 1985), is used to model the spectral variability of each of the basic sounds of the language using a mixture density Gaussian distribution (Juang *et al.*, 1986; Juang, 1985), which is optimally aligned with a speech training set and iteratively updated and improved (the means, variances, and mixture gains are iteratively updated) until an optimal alignment and match is achieved.

Figure 6 shows a simple three-state HMM for modeling the subword unit /s/ as spoken at the beginning of the word /six/. Each HMM state is characterized by a probability density function (usually a mixture Gaussian density) that characterizes the statistical behavior of the feature vectors at the beginning (state s1), middle (state s2), and end (state s3) of the sound /s/. In order to train the HMM for each subword unit, we use a labeled training set of words and sentences and utilize an efficient training procedure known as the Baum-Welch algorithm (Rabiner, 1989; Baum, 1972; Baum *et al.*, 1970) to align each of the various subword units with the spoken inputs, and then estimate the appropriate means, covariances, and mixture gains for the distributions in each subword unit state. The algorithm is a hill-climbing algorithm and is iterated until a stable alignment of subword unit models and speech is obtained, enabling the creation of stable models for each subword unit.

Figure 7 shows how a simple two-sound word, 'is,' which consists of the sounds /ih/ and /z/, is created by concatenating the models (Lee, 1989) for the /ih/ sound with the model for the /z/ sound, thereby creating a six-state model for the word 'is.'

Figure 8 shows how an HMM can be used to characterize a whole-word model (Lee *et al.*, 1989). In this

case, the word is modeled as a sequence of $M = 5$ HMM states, where each state is characterized by a mixture density, denoted as $b_j(\mathbf{x}_t)$ where the model state is the index j, the feature vector at time t is denoted as $\mathbf{x}_t$, and the mixture density is of the form:

$$
\begin{aligned}
b_j(\mathbf{x}_t) &= \sum_{k=1}^{K} c_{jk}\mathcal{N}[\mathbf{x}_t, \mu_{jk}, U_{jk}] \\
\mathbf{x}_t &= (x_{t1}, x_{t2}, \ldots, x_{tD}),\ D = 39 \\
K &= \text{number of mixture components in the density function} \\
c_{jk} &= \text{weight of } kth \text{ mixture component in state } j, c_{jk} \geq 0 \\
\mathcal{N} &= \text{Gaussian density function} \\
\mu_{jk} &= \text{mean vector for mixture } k,\ \text{state } j \\
U_{jk} &= \text{covariance matrix for mixture } k, \text{ state } j
\end{aligned}
$$

$$\sum_{k=1}^{K} c_{jk} = 1, \quad 1 \leq j \leq M$$

$$\int_{-\infty}^{\infty} b_j(\mathbf{x}_t)d\mathrm{x}_t = 1, \quad 1 \leq j \leq M$$

Included in Figure 8 is an explicit set of state transitions, a_{ij}, which specify the probability of making a transition from state i to state j at each frame, thereby defining the time sequence of the feature vectors over the duration of the word. Usually the self-transitions, a_{ii}, are large (close to 1.0), and the skip-state transitions, a_{13}, a_{24}, a_{35}, are small (close to 0).

Once the set of state transitions and state probability densities are specified, we say that a model λ (which is also used to denote the set of parameters that define the probability measure) has been created for the word or subword unit. (The model λ is often written as $\lambda(A, B, \pi)$ to explicitly denote the model parameters, namely $A = \{a_{ij}, 1 \leq i, j \leq M\}$, which is the state transition matrix, $B = \{b_j(x_t), 1 \leq j \leq M\}$, which is the state observation probability density, and $\pi = \{\pi_i, 1 \leq i \leq M\}$, which is the initial state distribution). In order to optimally train the various models (for each word unit [Lee *et al.*, 1989] or subword unit [Lee, 1989]), we need to have algorithms that perform the following three steps or tasks (Rabiner and Juang, 1985) using the acoustic observation sequence, X, and the model λ:

a. likelihood evaluation: compute $P(X|\lambda)$
b. decoding: choose the optimal state sequence for a given speech utterance
c. re-estimation: adjust the parameters of λ to maximize $P(X|\lambda)$.

Each of these three steps is essential to defining the optimal HMM models for speech recognition based on the available training data and each task if approached in a brute force manner would be computationally costly. Fortunately, efficient algorithms have been developed to enable efficient and accurate solutions to each of the three steps that must be performed to train and utilize HMM models in a speech recognition system. These are generally referred to as the forward-backward algorithm or the Baum-Welch re-estimation method (Levinson *et al.*, 1983). Details of the Baum-Welch procedure are beyond the scope of this article. The heart of the training procedure for re-estimating model parameters using the Baum-Welch procedure is shown in Figure 9.

Recently, the fundamental statistical method, while successful for a range of conditions, has been augmented with a number of techniques that attempt to further enhance the recognition accuracy and make the recognizer more robust to different talkers, background noise conditions, and channel effects. One family of such techniques focuses on transformation of the observed or measured features. The transformation is motivated by the need for vocal tract length normalization (e.g., reducing the impact of differences in vocal tract length of various speakers). Another such transformation (called the maximum likelihood linear regression method) can be embedded in the statistical model to account for a potential mismatch between the statistical characteristics of the training data and the actual unknown utterances to be recognized. Yet another family of techniques (e.g., the discriminative training method based on minimum classification error [MCE] or maximum mutual information [MMI]) aims at direct minimization of the recognition error during the parameter optimization stage.

Word Lexicon

The purpose of the word lexicon, or dictionary, is to define the range of pronunciation of words in the task vocabulary (Jurafsky and Martin, 2000; Riley *et al.*, 1999). The reason that such a word lexicon is necessary is because the same orthography can be pronounced differently by people with different accents, or because the word has multiple meanings that change the pronunciation by the context of its use. For example, the word 'data' can be pronounced as: /d/ /ae/ /t/ /ax/ or as /d/ /ey/ /t/ /ax/, and we would need

Figure 9 The Baum-Welch training procedure.

both pronunciations in the dictionary to properly train the recognizer models and to properly recognize the word when spoken by different individuals. Another example of variability in pronunciation from orthography is the word 'record,' which can be either a disk that goes on a player, or the process of capturing and storing a signal (e.g., audio or video). The different meanings have significantly different pronunciations. As in the statistical language model, the word lexicon (consisting of sequences of symbols) can be associated with probability assignments, resulting in a probabilistic word lexicon.

Language Model

The purpose of the language model (Rosenfeld, 2000; Jelinek *et al.*, 1991), or grammar, is to provide a task syntax that defines acceptable spoken input sentences and enables the computation of the probability of the word string, W, given the language model, i.e., $P_L(W)$. There are several methods of creating word grammars, including the use of rule-based systems (i.e., deterministic grammars that are knowledge-driven), and statistical methods that compute an estimate of word probabilities from large training sets of textual material. We describe the way in which a statistical N-gram word grammar is constructed from a large training set of text.

Assume we have a large text training set of labeled words. Thus for every sentence in the training set, we have a text file that identifies the words in that sentence. If we consider the class of N-gram word grammars, then we can estimate the word probabilities from the labeled text training set using counting methods. Thus to estimate word trigram probabilities (that is the probability that a word w_i was preceded by the pair of words (w_{i-1}, w_{i-2})), we compute this quantity as:

$$P(w_i|w_{i-1}, w_{i-2}) = \frac{C(w_{i-2}, w_{i-1}, w_i)}{C(w_{i-2}, w_{i-1})}$$

where $C(w_{i-2}, w_{i-1}, w_i)$ is the frequency count of the word triplet (i.e., trigram) consisting of (w_{i-2}, w_{i-1}, w_i) that occurred in the training set, and $C(w_{i-2}, w_{i-1})$ is the frequency count of the word duplet (i.e., bigram) (w_{i-2}, w_{i-1}) that occurred in the training set.

Although the method of training N-gram word grammars, as described above, generally works quite well, it suffers from the problem that the counts of N-grams are often highly in error due to problems of data sparseness in the training set. Hence for a text training set of millions of words, and a word vocabulary of several thousand words, more than 50% of word trigrams are likely to occur either once or not at all in the training set. This leads to gross distortions in the computation of the probability of a word string, as required by the basic Bayesian recognition algorithm. In the cases when a word trigram does not occur at all in the training set, it is unacceptable to define the trigram probability as 0 (as would be required by the direct definition above), since this leads to effectively invalidating all strings with that particular trigram from occurring in recognition. Instead, in the case of estimating trigram word probabilities (or similarly extended to N-grams where N is more than three), a smoothing algorithm (Bahl *et al.*, 1983) is applied by interpolating trigram, bigram, and unigram relative frequencies, i.e.,

$$\hat{P}(w_i|w_{i-1}, w_{i-2}) = p_3 \frac{C(w_{i-2}, w_{i-1}, w_i)}{C(w_{i-2}, w_{i-1})} + p_2 \frac{C(w_{i-1}, w_i)}{C(w_{i-1})} + p_1 \frac{C(w_i)}{\sum_i C(w_i)}$$

$$p_3 + p_2 + p_1 = 1$$

$$\sum_i C(w_i) = \text{size of text training corpus}$$

where the smoothing probabilities, p_3, p_2, p_1 are obtained by applying the principle of cross-validation. Other schemes such as the Turing-Good

Figure 10 Bigram language perplexity for Encarta Encyclopedia.

estimator, which deals with unseen classes of observations in distribution estimation, have also been proposed (Nadas, 1985).

Worth mentioning here are two important notions that are associated with language models: perplexity of the language model and the rate of occurrences of out-of-vocabulary words in real data sets. We elaborate them below.

Language Perplexity A measure of the complexity of the language model is the mathematical quantity known as language perplexity (which is actually the geometric mean of the word branching factor, or the average number of words that follow any given word of the language) (Roukos, 1998). We can compute language perplexity, as embodied in the language model, $P_L(W)$, where $W = (w_1, w_2, \ldots, w_Q)$ is a length-Q word sequence, by first defining the entropy (Cover and Thomas, 1991) as:

$$H(W) = -\frac{1}{Q}\log_2 P(W)$$

Using a trigram language model, we can write the entropy as:

$$H(W) = -\frac{1}{Q}\sum_{i=1}^{Q}\log_2 P(w_i|w_{i-1}, w_{i-2})$$

where we suitably define the first couple of probabilities as the unigram and bigram probabilities. Note that as Q approaches infinity, the above entropy approaches the asymptotic entropy of the source defined by the measure $P_L(W)$. The perplexity of the language is then defined as:

$$PP(W) = 2^{H(W)} = P(w_1, w_2, \ldots, w_Q)^{-1/Q} \quad \text{as } Q \to \infty.$$

Some examples of language perplexity for specific speech recognition tasks are the following:

- For an 11-digit vocabulary ('zero' to 'nine' plus 'oh') where every digit can occur independently of every other digit, the language perplexity (average word branching factor) is 11.
- For a 2000-word Airline Travel Information System (ATIS) [Ward, 1991], the language perplexity (using a trigram language model) is 20 [Price, 1990].
- For a 5000-word *Wall Street Journal* task (reading articles aloud), the language perplexity (using a bigram language model) is 130 [Paul *et al.*, 1992].

A plot of the bigram perplexity for a training set of 500 million words, tested on the Encarta Encyclopedia is shown in Figure 10. It can be seen that language perplexity grows only slowly with the vocabulary size and is only about 400 for a 60 000-word vocabulary. (Language perplexity is a complicated function of vocabulary size and vocabulary predictability, and is not in any way directly proportional to vocabulary size).

Out-of-Vocabulary Rate Another interesting aspect of language models is their coverage of the language as exemplified by the concept of an out-of-vocabulary (OOV) (Kawahara and Lee, 1998) rate, which measures how often a new word appears for a specific task, given that a language model of a given vocabulary size for the task has been created. Figure 11 shows the OOV rate for sentences from the Encarta Encyclopedia, again trained on 500 million words of text, as a function of the vocabulary size. It can be seen that even for a 60 000-word vocabulary, about 4% of the words that are encountered have not been seen previously and thus are considered OOV words (which, by definition, cannot be recognized correctly by the recognition system).

Pattern Matching

The job of the pattern matching module is to combine information (probabilities) from the acoustic model, the language model, and the word lexicon to find the

Figure 11 Out-of-vocabulary rate of Encarta Encyclopedia as a function of the vocabulary size.

Figure 12 Use of WFSTs to compile FSN to minimize redundancy in the network.

'optimal' word sequence, i.e., the word sequence that is consistent with the language model and that has the highest probability among all possible word sequences in the language (i.e., best matches the spectral feature vectors of the input signal). To achieve this goal, the pattern matching system is actually a decoder (Ney, 1984; Paul, 2001; Mohri, 1997) that searches through all possible word strings and assigns a probability score to each string, using a Viterbi decoding algorithm (Forney, 1973) or its variants.

The challenge for the pattern matching module is to build an efficient structure (via an appropriate finite state network or FSN) (Mohri, 1997) for decoding and searching large-vocabulary complex-language models for a range of speech recognition tasks. The resulting composite FSNs represent the cross-product of the features (from the input signal), with the HMM states (for each sound), with the HMM units (for each sound), with the sounds (for each word), with the words (for each sentence), and with the sentences (those valid within the syntax and semantics of the task and language). For large-vocabulary high-perplexity speech recognition tasks, the size of the network can become astronomically large and has been shown to be on the order of 10^{22} states for some tasks. Such networks are prohibitively large and cannot be exhaustively searched by any known method or machine. Fortunately there are methods (Mohri, 1997) for compiling such large networks and reducing the size significantly due to inherent redundancies and overlaps across each of the levels of the network. (One earlier example of taking advantage of the search redundancy is the dynamic programming method (Bellman, 1957), which turns an otherwise exhaustive search problem into an incremental one.) Hence the network that started with 10^{22} states was able to be compiled down to a mathematically equivalent network of 10^{8} states that was readily searched for the optimum word string with no loss of performance or word accuracy.

The way in which such a large network can be theoretically (and practically) compiled to a much smaller network is via the method of weighted finite state transducers (WFST), which combine the various representations of speech and language and optimize the resulting network to minimize the number of search states. A simple example of such a WFST is given in Figure 12, and an example of a simple word pronunciation transducer (for two versions of the word 'data') is given in Figure 13.

Using the techniques of composition and optimization, the WFST uses a unified mathematical framework to efficiently compile a large network into a minimal representation that is readily searched using standard Viterbi decoding methods. The example of Figure 13 shows how all redundancy is removed and a minimal search network is obtained, even for as simple an example as two pronunciations of the word 'data.'

Confidence Scoring

The goal of the confidence scoring module is to post-process the speech feature set in order to identify possible recognition errors as well as out-of-vocabulary events and thereby to potentially improve the performance of the recognition algorithm. To achieve this goal, a word confidence score (Rahim *et al.*, 1997) based on a simple likelihood ratio hypothesis testing associated with each recognized word, is performed and the word confidence score is used to determine which, if any, words are likely to be incorrect because of either a recognition error or because it

Figure 13 Word pronunciation transducer for two pronunciations of the word 'data.'

was an OOV word (that could never be correctly recognized). A simple example of a two-word phrase and the resulting confidence scores is as follows:

Spoken Input: credit please
Recognized String: credit fees
Confidence Scores: (0.9) (0.3)

Based on the confidence scores (derived using a likelihood ratio test), the recognition system would realize which word or words are likely to be in error and take appropriate steps (in the ensuing dialog) to determine whether an error had been made and how to fix it so that the dialog moves forward to the task goal in an orderly and proper manner. (We will discuss how this happens in the discussion of dialog management later in this article.)

Simple Example of ASR System: Isolated Digit Recognition

To illustrate some of the ideas presented above, consider a simple isolated word speech recognition system where the vocabulary is the set of 11 digits ('zero' to 'nine' plus the word 'oh' as an alternative for 'zero') and the basic recognition unit is a whole word model. For each of the 11 vocabulary words, we must collect a training set with sufficient, say K, occurrences of each spoken word so as to be able to train reliable and stable acoustic models (the HMMs) for each word. Typically a value of $K = 5$ is sufficient for a speaker-trained system (that is a recognizer that works only for the speech of the speaker who trained the system). For a speaker-independent recognizer, a significantly larger value of K is required to completely characterize the variability in accents, speakers, transducers, environments, etc. For a speaker-independent system based on using only a single transducer (e.g., a telephone line input), and a carefully controlled acoustic environment (low noise), reasonable values of K are on the order of 100–500 for training reliable word models and obtaining good recognition performance.

For implementing an isolated-word recognition system, we do the following:

1. For each word, v, in the vocabulary, we build a word-based HMM, λ_v, i.e., we must (re-)estimate the model parameters λ_v that optimize the likelihood of the K training vectors for the v-th word. This is the training phase of the system.
2. For each unknown (newly spoken) test word that is to be recognized, we measure the feature vectors (the observation sequence), $X = [\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_N]$ (where each observation vector, $\mathbf{x}_i$ is the set of MFCCs and their first- and second-order derivatives), we calculate model likelihoods, $P(X|\lambda_v)$, $1 \le v \le V$ for each individual word model (where V is 11 for the digits case), and then we select as the recognized word the word whose model likelihood score is highest, i.e., $v = \arg\max_{1 \le v \le V} P(X|\lambda_v)$. This is the testing phase of the system.

Figure 14 shows a block diagram of a simple HMM-based isolated word recognition system.

Performance of Speech Recognition Systems

A key issue in speech recognition (and understanding) system design is how to evaluate the system's performance. For simple recognition systems, such as the isolated word recognition system described in the previous section, the performance is simply the word error rate of the system. For more complex speech recognition tasks, such as for dictation applications, we must take into account the three types of errors that can occur in recognition, namely word insertions (recognizing more words than were actually spoken), word substitutions (recognizing an incorrect word in place of the correctly spoken word), and word deletions (recognizing fewer words than were actually spoken) (Pallet and Fiscus, 1997). Based on the criterion of equally weighting all three types of errors, the conventional definition of word error rate for most speech recognition tasks is:

$$WER = \frac{NI + NS + ND}{|W|}$$

where NI is the number of word insertions, NS is the number of word substitutions, ND is the number of word deletions, and $|W|$ is the number of words in the sentence W being scored. Based on the above definition of word error rate, the performance of a range of speech recognition and understanding systems is shown in Table 1.

It can be seen that for a small vocabulary (11 digits), the word error rates are very low (0.3%) for a connected digit recognition task in a very clean environment (TI database) (Leonard, 1984), but we

Figure 14 HMM-based Isolated word recognizer.

Table 1 Word error rates for a range of speech recognition systems

Corpus	*Type of speech*	*Vocabulary size*	*Word error rate*
Connect digit string (TI database)	Spontaneous	11 (0–9, oh)	0.3%
Connect digit string (AT&T mall recordings)	Spontaneous	11 (0–9, oh)	2.0%
Connected digit string (AT&T HMIHY)	Conversational	11 (0–9, oh)	5.0%
Resource management (RM)	Read speech	1000	2.0%
Airline travel information system (ATIS)	Spontaneous	2500	2.5%
North American business (NAB & WSJ)	Read text	64 000	6.6%
Broadcast news	Narrated news	210 000	~15%
Switchboard	Telephone conversation	45 000	~27%
Call-home	Telephone conversation	28 000	~35%

see that the digit word error rate rises significantly (to 5.0%) for connected digit strings recorded in the context of a conversation as part of a speech understanding system (HMIHY©) (Gorin *et al.*, 1996). We also see that word error rates are fairly low for 1000- to 2500-word vocabulary tasks (RM [Linguistic Data Consortium, 1992–2000] and ATIS [Ward, 1991]) but increase significantly as the vocabulary size rises (6.6% for a 64 000-word NAB vocabulary, and 13–17% for a 210 000-word broadcast news vocabulary), as well as for more colloquially spoken speech (Switchboard and Call-home [Godfrey *et al.*, 1992]), where the word error rates are much higher than comparable tasks where the speech is more formally spoken.

Figure 15 illustrates the reduction in word error rate that has been achieved over time for several of the tasks from Table 1 (as well as other tasks not covered in Table 1). It can be seen that there is a steady and systematic decrease in word error rate (shown on a logarithmic scale) over time for every system that has been extensively studied. Hence it is generally believed that virtually any (task-oriented) speech recognition system can achieve arbitrarily low error (over time) if sufficient effort is put into finding appropriate techniques for reducing the word error rate.

If one compares the best ASR performance for machines on any given task with human performance (which often is hard to measure), the resulting comparison (as seen in Figure 16) shows that humans outperform machines by factors of between 10 and 50; that is the machine achieves word error rates that are larger by factors of 10–50. Hence we still have a long way to go before machines outperform humans on speech recognition tasks. However, one should

Figure 15 Reductions in speech recognition word error rates over time for a range of task-oriented systems (Pallet *et al.*, 1995).

Figure 16 Comparison of human and machine speech recognition performance for a range of speech recognition tasks (Lippman, 1997).

also note that under a certain condition an automatic speech recognition system could deliver a better service than a human. One such example is the recognition of a long connected digit string, such as a credit card's 16-digit number, that is uttered all at once; a human listener would not be able to memorize or jot down the spoken string without losing track of all the digits.

Spoken Language Understanding

The goal of the spoken language understanding module of the speech dialog circle is to interpret the meaning of key words and phrases in the recognized speech string, and to map them to actions that the speech understanding system should take. For speech understanding, it is important to recognize that in domain-specific applications highly accurate understanding can be achieved without correctly recognizing every word in the sentence. Hence a speaker can have spoken the sentence: *I need some help with my computer hard drive* and so long as the machine correctly recognized the words *help* and *hard drive*, it basically understands the context of the sentence (needing help) and the object of the context (hard drive). All of the other words in the sentence can often be misrecognized (although not so badly that other contextually significant words are recognized) without affecting the understanding of the meaning of the sentence. In this sense, keyword spotting (Wilpon *et al.*, 1990) can be considered a primitive form of speech understanding, without involving sophisticated semantic analysis.

Spoken language understanding makes it possible to offer services where the customer can speak naturally without having to learn a specific vocabulary

and task syntax in order to complete a transaction and interact with a machine (Juang and Furui, 2000). It performs this task by exploiting the task grammar and task semantics to restrict the range of meanings associated with the recognized word string, and by exploiting a predefined set of 'salient' words and phrases that map high-information word sequences to this restricted set of meanings. Spoken language understanding is especially useful when the range of meanings is naturally restricted and easily cataloged so that a Bayesian formulation can be used to optimally determine the meaning of the sentence from the word sequence. This Bayesian approach utilizes the recognized sequence of words, W, and the underlying meaning, C, to determine the probability of each possible meaning, given the word sequence, namely:

$$P(C|W) = P(W|C)P(C)/P(W)$$

and then finding the best conceptual structure (meaning) using a combination of acoustic, linguistic and semantic scores, namely:

$$C^* = \arg\max_C P(W|C)P(C)$$

This approach makes extensive use of the statistical relationship between the word sequence and the intended meaning.

One of the most successful (commercial) speech understanding systems to date has been the AT&T How May I Help You (HMIHY) task for customer care. For this task, the customer dials into an AT&T 800 number for help on tasks related to his or her long distance or local billing account. The prompt to the customer is simply: 'AT&T. How May I Help You?' The customer responds to this prompt with totally unconstrained fluent speech describing the reason for calling the customer care help line. The system tries to recognize every spoken word (but invariably makes a very high percentage of word errors), and then utilizes the Bayesian concept framework to determine the meaning of the speech. Fortunately, the potential meaning of the spoken input is restricted to one of several possible outcomes, such as asking about Account Balances, or new Calling Plans, or changes in local service, or help for an Unrecognized Number, etc. Based on this highly limited set of outcomes, the spoken language component determines which meaning is most appropriate (or else decides not to make a decision but instead to defer the decision to the next cycle of the dialog circle), and appropriately routes the call. The dialog manager, spoken language generation, and text-to-speech modules complete the cycle based on the meaning determined by the spoken language understanding box. A simple characterization of the HMIHY system is shown in Figure 17.

The major challenge in spoken language understanding is to go beyond the simple classification task of the HMIHY system (where the conceptual meaning is restricted to one of a fixed, often small, set of choices) and to create a true concept and meaning understanding system.

While this challenge remains in an embryonic stage, an early attempt, namely the Air Travel Information System (ATIS), was made in embedding speech recognition in a stylized semantic structure to mimic a natural language interaction between human and a machine. In such a system, the semantic notions encapsulated in the system are rather limited, mostly in terms of originating city and destination city names, fares, airport names, travel times and so on, and can be directly instantiated in a semantic template without much text analysis for understanding. For example, a typical semantic template or network is shown in Figure 18 where the relevant notions, such as the departing city, can be easily identified and used in dialog management to create the desired user interaction with the system.

Dialog Management, Spoken Language Generation, and Text-to-Speech Synthesis

The goal of the dialog management module is to combine the meaning of the current input speech

Figure 17 Conceptual representation of HMIHY (How May I Help You?) system.

with the current state of the system (which is based on the interaction history with the user) in order to decide what the next step in the interaction should be. In this manner, the dialog management module makes viable fairly complex services that require multiple exchanges between the system and the customer. Such dialog systems can also handle user-initiated topic switching within the domain of the application.

The dialog management module is one of the most crucial steps in the speech dialog circle for a successful transaction as it enables the customer to accomplish the desired task. The way in which the dialog management module works is by exploiting models of dialog to determine the most appropriate spoken text string to guide the dialog forward toward a clear and well-understood goal or system interaction. The computational models for dialog management include both structure-based approaches (which models dialog as a predefined state transition network that is followed from an initial goal state to a set of final goal states), or plan-based approaches (which consider communication as executing a set of plans that are oriented toward goal achievement).

The key tools of dialog strategy are the following:

- Confirmation: used to ascertain correctness of the recognized and understood utterances
- Error recovery: used to get the dialog back on track after a user indicates that the system has misunderstood something
- Reprompting: used when the system expected input but did not receive any input
- Completion: used to elicit missing input information from the user
- Constraining: used to reduce the scope of the request so that a reasonable amount of information is retrieved, presented to the user, or otherwise acted upon
- Relaxation: used to increase the scope of the request when no information has been retrieved
- Disambiguation: used to resolve inconsistent input from the user
- Greeting/Closing: used to maintain social protocol at the beginning and end of an interaction
- Mixed initiative: allows users to manage the dialog flow.

Although most of the tools of dialog strategy are straightforward and the conditions for their use are fairly clear, the mixed initiative tool is perhaps the most interesting one, as it enables a user to manage the dialog and get it back on track whenever the user feels the need to take over and lead the interactions with the machine. Figure 19 shows a simple chart that illustrates the two extremes of mixed initiative for a simple operator services scenario. At the one extreme, where the **system** manages the dialog totally, the system responses are simple declarative requests to elicit information, as exemplified by the system command "Please say collect, calling card, third number". At the other extreme is **user** management of the dialog where the system responses are open ended and the customer can freely respond to the system command 'How may I help you?'

Figure 20 illustrates some simple examples of the use of system initiative, mixed initiative, and user initiative for an airlines reservation task. It can be seen that system initiative leads to long dialogs (due to the limited information retrieval at each query), but the dialogs are relatively easy to design, whereas user initiative leads to shorter dialogs (and hence a better user experience), but the dialogs are more difficult to design. (Most practical natural language systems need to be mixed initiative so as to be able to change initiatives from one extreme to another, depending on the state of the dialog and how successfully things have progressed toward the ultimate understanding goal.)

Dialog management systems are evaluated based on the speed and accuracy of attaining a well-defined

Figure 18 An example of a word grammar with embedded semantic notions in ATIS.

Figure 19 Illustration of mixed initiative for operator services scenario.

task goal, such as booking an airline reservation, renting a car, purchasing a stock, or obtaining help with a service.

The spoken language generation module translates the action of the dialog manager into a textual representation and the text-to-speech modules convert the textual representation into natural-sounding speech to be played to the user so as to initiate another round of dialog discussion or to end the query (hopefully successfully).

User Interfaces and Multimodal Systems

The user interface for a speech communications system is defined by the performance of each of the blocks in the speech dialog circle. A good user interface is essential to the success of any task-oriented system, providing the following capabilities:

- It makes the application easy to use and robust to the kinds of confusion that arise in human–machine communications by voice.
- It keeps the conversation moving forward, even in periods of great uncertainty on the parts of either the user or the machine.
- Although it cannot save a system with poor speech recognition or speech understanding performance, it can make or break a system with excellent speech recognition and speech understanding performance.

Although we have primarily been concerned with speech recognition and understanding interfaces to machines, there are times when a multimodal approach to human–machine communications is both necessary and essential. The potential modalities that can work in concert with speech include gesture and pointing devices (e.g., a mouse, keypad, or stylus). The selection of the most appropriate user interface mode (or combination of modes) depends on the device, the task, the environment, and the user's abilities and preferences. Hence, when trying to identify objects on a map (e.g., restaurants, locations of subway stations, historical sites), the use of a pointing device (to indicate the area of interest) along with speech (to indicate the topic of interest) often is a good user interface, especially for small computing devices like tablet PCs or PDAs. Similarly, when entering PDA-like information (e.g., appointments, reminders, dates, times, etc.) onto a small handheld device, the use of a stylus to indicate the appropriate

Figure 20 Examples of mixed initiative dialogs.

type of information with voice filling in the data field is often the most natural way of entering such information (especially as contrasted with stylus-based text input systems such as graffiti for Palm-like devices). Microsoft research has shown the efficacy of such a solution with the MIPad (Multimodel Interactive Pad) demonstration, and they claim to have achieved double the throughput for English using the multimodal interface over that achieved with just a pen stylus and the graffiti language.

Summary

In this article we have outlined the major components of a modern speech recognition and spoken language understanding system, as used within a voice dialog system. We have shown the role of signal processing in creating a reliable feature set for the recognizer and the role of statistical methods in enabling the recognizer to recognize the words of the spoken input sentence as well as the meaning associated with the recognized word sequence. We have shown how a dialog manager utilizes the meaning accrued from the current as well as previous spoken inputs to create an appropriate response (as well as potentially taking some appropriate actions) to the customer request(s), and finally how the spoken language generation and text-to-speech synthesis parts of the dialog complete the dialog circle by providing feedback to the user as to actions taken and further information that is required to complete the transaction that is requested.

Although we have come a long way toward the vision of Hal, the machine that both recognizes words reliably and understands their meaning almost flawlessly, we still have a long way to go before this vision is fully achieved. The major problem that must yet be tackled is robustness of the recognizer and the language understanding system to variability in speakers, accents, devices, and environments in which the speech is recorded. Systems that appear to

work almost flawlessly under laboratory conditions often fail miserably in noisy train or airplane stations, when used with a cellphone or a speakerphone, when used in an automobile environment, or when used in noisy offices. There are many ideas that have been advanced for making speech recognition more robust, but to date none of these ideas has been able to fully combat the degradation in performance that occurs under these nonideal conditions.

Speech recognition and speech understanding systems have made their way into mainstream applications and almost everybody has used a speech recognition device at one time or another. They are widely used in telephony applications (operator services, customer care), in help desks, in desktop dictation applications, and especially in office environments as an aid to digitizing reports, memos, briefs, and other office information. As speech recognition and speech understanding systems become more robust, they will find their way into cellphone and automotive applications, as well as into small devices, providing a natural and intuitive way to control the operation of these devices as well as to access and enter information.

Speech Synthesis

We think of speech as a uniquely human ability. It is the primary medium of exchange for most social interactions among humans, and its evolution from animal communications is still not understood. However, the claim that speech is uniquely human depends on a specific interpretation of what speech is. If we take the view that speech is any acoustic pattern that can be heard by a listener as consisting of a sequence of phonetic segments, then the constraint of being uniquely human is significantly relaxed. It is well known that a variety of different species of nonhuman animals, with a wide range of vocal systems, can produce acoustic patterns that we can hear as speech. From Irene Pepperberg's African gray parrot Alex (*see* **Communication in Grey Parrots**) to the Indian hill mynah bird described by Klatt and Stefanski (1974) to Hoover the talking harbor seal (Friend, 2004), animals can produce acoustic patterns that human listeners can hear and interpret as speech. Although some speech sounds are said to be outside the capability of vocal production by some animals (see Lieberman, 1991 regarding the vowel space limitations of nonhuman primates and dogs), it has been claimed that Alexander Graham Bell trained his dog to produce speech sounds. He trained his dog to growl at a low constant level and then shaped the dog's articulators by hand to generate a few syllables. Bell reported that the culmination of his sky terrier's ability was to produce with a little manual assistance 'ow ah oo ga ma ma' for 'How are you grandmamma?' While speech production is specifically thought of as humans talking, we can think of speech synthesis as the process of producing the acoustic patterns of speech by nonhuman means.

However, at the late date of the early 1900s (ca. 1910), Bell's talking dog was not the first attempt at synthesizing speech. The Frankenstein notion of violating the sanctity of human uniqueness by synthesizing speech dates back to 1791 with Wolfgang von Kempelen's speaking machine (*see* **Kempelen, Wolfgang von (1734–1804)**). As with Bell's canine synthesizer, von Kempelen's was a mechanical synthesizer in which a source of air vibration (from a bellows past vocal chords simulated by an oscillating reed) was shaped by varying the resonance properties of the simulated mouth by covering the mouth with a hand or inserting a thumb. The synthesizer could produce some speech sounds, whole words, and even short sentences.

As early examples of speech synthesizers, Bell's terrier and von Kempelen's speaking machine share some basic principles of human speech production with most current speech synthesizers. These principles of operation are described generally by the source-filter theory of speech production. Using larynxes excised from cadavers, Johannes Muller (1848) observed that the sounds emitted directly from an excised larynx are different from actual speech sounds. Furthermore, these sounds could be rendered more speech-like using a tube to shape the spectral properties of the sound. The source-filter theory of speech production (Fant, 1960; Flanagan, 1972) describes the acoustic speech signal as the result of convolving an acoustic source (either periodic excitation such as voicing or aperiodic noise) with a spectral transfer function (corresponding to the coupled resonators of the vocal tract) and a radiation characteristic function (corresponding to radiation at the lips). Bell's terrier's growling provided a periodic source that was shaped through the vocal tract while Bell manipulated the articulators. In much the same way, speech synthesizers (whether mechanical hardware or electronics or software) combine a source function (either periodic as produced by a model of laryngeal vibration or noise as turbulence produced at the glottis) with a model of changes in vocal tract shape (represented either as resonators, parallel or coupled, or as articulators) to produce a speech waveform. What differs between synthesizers is the method by which this procedure is carried out.

Methods of Speech Synthesis

The modern history of speech synthesis dates back over half a century (see Klatt, 1987 for a comprehensive review) and over that time, encompasses a broad range of different technologies, from simulating vocal tracts to the pattern-playback machine at Haskins Laboratories. However, if we take speech synthesis as depending on some form of source-filter theory, in simulation of human speech production, we exclude some things from the realm of speech synthesis. For example, any simple acoustic reproduction medium such as audio tape or a digitized waveform can easily generate a speech signal. However, there is no model of speech production inherent in this process – a recorded waveform is retransmitted from stored form to some analog of acoustic pressure variation. Thus, while it is possible to reduce the information contained in an acoustic waveform by various coding

methods (e.g., MP3) for efficient storage purposes, the extraction of this kind of parametric description need not be in terms of source-filter theory. On the other hand, it is possible to achieve relatively high efficiency in storing speech encoded in a form that can serve as input to a speech synthesizer. The limit can be seen simply by considering the size of a text document (that can be read aloud by a human) and the corresponding waveform captured in the fidelity of a compact disc.

Taking speech synthesis to be based on the source-filter theory of speech production does not place very strong constraints on the methods of synthesis, clearly. There are currently three methods used to generate synthetic speech. Conceptually, articulatory synthesis is perhaps the most straightforward method. Articulatory synthesizers model the speech production process in terms of the mechanical motions of the articulators and the changes in sound pressure throughout the anatomical structures used in speech production. As such, articulatory synthesizers are intended to closely match the physical process of talking. By contrast, formant synthesizers model speech production in terms of a mathematical description of the acoustic process of speech production (Klatt, 1980). Instead of representing the vocal tract as a physical object with the shape and movement constraints found in anatomy, the vocal tract is represented as a set of resonators. Vocalic and aperiodic sources are represented mathematically as time-varying signals without the specific physical interpretations of pressure, for example. Of course, the resonators in a formant synthesizer correspond to the resonant and filtering acoustic properties of the vocal tract and articulators, but are described more in terms of a transfer function than in terms of area or volume of the vocal tract. Finally, 'analytic' synthesis models generate speech from a parametric source-filter analysis (typically using Linear Prediction Coding, LPC) as the basis. In this approach, the synthesis models a specific acoustic waveform rather than the production process or the acoustic characterization of the production process. However, the model of the utterance is in terms of a hypothetical source function and a vocal tract transfer function or filter to shape the source output. Thus, in all three methods, a synthetic utterance is generated by modeling a real utterance (in the analytic method) or an idealization of a real utterance (as in articulatory or formant synthesis). The primary difference is the derivation and nature of the parameters used in the modeling process.

Articulatory synthesizers are not new (see Klatt, 1987 for reviews) dating back over 50 years. For an articulatory synthesizer, the parameters reflect real time-varying physical properties of the vocal tract during speech production. Although there is generally some control over aspects of the source function, the primary parameters of interest govern the shape of the vocal tract over time that serves to shape or filter the source. Articulation then is typically realized by time-varying descriptions of the vocal tract. These physical properties might be measured using any of a number of radiological methods, for example, recently using magnetic resonance imaging (MRI) of a vocal tract during speech production or other articulatory data. Models such as ASY developed at Haskins Laboratories (Rubin *et al.*, 1981) use parameters specifying the crosssectional (midsaggital) area of the vocal tract in terms of the position of the jaw, velum, tongue body, tongue tip, lips, and hyoid bone. Other current models allow a different specification of vocal tract crosssectional area or a combination of vocal tract constriction areas along with other parameters such as subglottal pressure and source characteristics such as fundamental frequency, F0 (HLsyn, Sensimetrics Corp., 1995). It is interesting to note that this last example, HLsyn translates the articulatory parameters into their formant-synthesis parameter equivalents, making explicit that there is a close correspondence between the articulatory events and the acoustic characterization of those events. In part, one could say that the difference between an articulatory and formant synthesizer is simply the terms in which one wants to think about the process of speech production and the characterization of parameters one wants to use for controlling the synthesizer.

Although there have been a number of formant synthesizers developed and described in past decades (see Klatt, 1980, 1987 for reviews), the definitive model was described by Klatt's (1980) cascade/parallel formant synthesizer. As with an articulatory synthesizer, there is some control over the source function (e.g., the frequency and amplitude of F0 at different time points) but the primary work is carried out by the set of resonators that define the vocal tract transfer function (the filter) at each point in time. In a formant synthesizer, a vocal tract function is specified by setting the center frequencies and bandwidths of a set of resonators. These parameters can be set on a time frame (e.g., 5 ms) that specifies the rate of control of the vocal tract change in the synthesizer. Changing the center frequencies and bandwidths of these resonators over time is functionally equivalent to changing the vocal tract crosssectional area function over time. However, these parameters can be measured directly from a spectrogram of speech rather than from radiographic measurements of the vocal tract of a talker speaking.

In a parallel formant synthesizer, the resonators separately and independently shape the source, with the outputs summed together before the radiation characteristic (simulating the radiation at the lips that rolls off the higher frequencies). The amplitudes of each resonator are set separately and are chosen to match the relative formant peaks in a smoothed spectrum of a target utterance such as a vowel. In a cascade formant synthesizer, the resonators are coupled in series, so the output of one serves as the input for the next. This process more closely simulates the acoustic coupling of resonators in a real vocal tract, automatically adjusting the relative amplitudes of each resonator's contribution. While a parallel synthesizer can, in principle, model the output of a cascade synthesizer, the output has to be more closely matched to the frequency-amplitude profile of the spectrum at each time point, thereby requiring many more amplitude parameters to be set manually (one per resonator). In Klatt's (1980) cascade/parallel formant synthesizer, there are two branches available for synthesis simultaneously – a cascade formant synthesizer and a parallel formant synthesizer – and the outputs of the two branches are combined before the radiation characteristic is imposed.

The advantage of the cascade/parallel formant synthesizer design, aside from the convenience of choosing whichever approach is desired for any particular utterance, is that it is possible to synthesize a syllable such as /sta/ more easily, using the parallel branch to model the fricative /s/ (using a frication source at the simulated constriction), setting resonators to the frequencies of the fricative poles and the cascade branch to more accurately model the /ta/. This ability also allows for more easily and accurately synthesizing mixed-source consonants such as voiced fricatives. Klatt's (1980) description of the cascade/parallel formant synthesizer included an appendix specifying the FORTRAN source code to implement the synthesizer. Since that publication, Nick Ing-Simons and Jon Iles rewrote the synthesizer in C and made it widely available, and there have been a number of other implementations of this synthesizer as well.

In order to synthesize an utterance using either an articulatory synthesizer or a formant synthesizer, it is necessary to model either the process of speech production, or the acoustic consequences of that process. This requirement means that it is necessary to have either anatomical or acoustic data corresponding to the utterance to be modeled, or to components of the utterance. The process of synthesis is one of setting the parameters for the time-varying changes in the source and the time-varying changes in the vocal tract. An alternative method is to actually measure those parameters from an utterance and use the measurements to synthesize an utterance. Linear Prediction Coding (LPC) is a method of speech analysis that is based on source-filter theory, separately estimating on a short-time basis properties of the source function and the vocal tract transfer function (Atal and Hanauer, 1971). LPC analysis fits the short-time spectrum with a linear model based on the assumption that the vocal tract can be represented by a small number of connected, fixed volume tubes and certain constraining assumptions about the source function at any point in time. The result of this analysis is a parametric characterization of the vocal tract transfer function and the source function for each time point in the analysis. The target utterance can then be synthesized by combining the source model with the vocal tract transfer model. The resulting synthetic speech is very high in quality, quite similar in sound to the original utterance, which should not be surprising. Indeed, sometimes this result is referred to as 'resynthesis' of the utterance rather than synthesis, given that the parameters used to drive the synthesis were directly computed from an analysis of the target utterance itself. This form of synthesis is the inverse of the analysis process.

On the surface, this kind of speech synthesis seems extremely close to simply encoding and reproducing speech. Indeed, it seems quite comparable to Fourier analysis and synthesis or wavelet analysis and synthesis. Depending on the window size (in time), Fourier analysis will yield the moment-by-moment power spectra corresponding to any arbitrary waveform. By inversion, Fourier analysis will reconstruct the original wave from a series of these spectral slices. However, Fourier analysis does not make any *a priori* assumptions about the method by which the target waveform was generated. It works as well for speech as for a violin concerto. By contrast, LPC analysis and synthesis makes strong and specific assumptions regarding the source-filter theory of speech production, assuming and estimating the source function and the vocal tract transfer function. In doing so, the parametric model that results from this analysis is in a form that is compatible with most theories of speech production. For example, the results of LPC analysis could essentially set the parameters of a formant synthesizer, whereas the Fourier analysis does not separate out the effects of source and vocal tract transfer function.

This estimation provides two important advantages for synthesis by analysis. First, for the kind of articulatory and formant synthesis systems described, parameters have to be entered on a moment-by-moment basis. For example, for the Klatt synthesizer, parameters have to be entered for every 5 ms of an utterance. Meeting this requirement means that even

synthesizing a 200 ms syllable is a laborious process. However, for LPC synthesis, the parameters are provided as a result of the LPC analysis, making it possible to synthesize much longer utterances, including sentences or discourse. Second, by explicitly modeling separate source and vocal tract transfer functions, the parameters are not only available for direct use in resynthesis of an analyzed utterance, but they are also available for manipulation. This availability means that it is possible to modify parameters corresponding to aspects of prosody or phonetics opening up more possible applications than would be available for simple reproduction of a coded utterance.

Applications of Speech Synthesis

This ability to modify the parametric description of an utterance provides an important way to control the source and acoustic–phonetic characteristics of speech. As a result, one of the most important applications of these speech synthesizers is for research on spoken language. Linguists, cognitive psychologists, engineers, and speech and hearing scientists have used speech synthesis as a basic tool for carrying out experiments. The first basic studies of categorical perception (see Liberman *et al.*, 1967 for a review) were carried out using the Pattern Playback Machine at Haskins Laboratories. Developed as part of a project to construct a reading machine for the blind, the Pattern Playback essentially inverted the operation of a spectrograph. Spectrograms (time by frequency by amplitude graphs) that were hand-painted on a clear acetate belt were converted to speech by converting light shining through the spectrograms into time-varying speech waveforms represented as electrical signals. By making small changes in the painted spectrogram, small changes in the acoustic structure were created. The ability to make small constant changes in the pattern structure of a syllable made it possible to carry out studies that would have been inconceivable otherwise. Liberman *et al.* (1957) used such small systematic acoustic variations to create a series of stimuli varying in initial consonant. They demonstrated that discrimination of these acoustic variations did not monotonically follow the mean frequency of the differences. As frequency increases, for a constant acoustic difference between pairs of nonspeech stimuli, discrimination performance should follow Weber's Law; discrimination performance should diminish, if the frequency range is great enough. Instead, Liberman *et al.* found that discrimination was nonmonotonic, depending more on the phonemic labels given to the stimuli than the frequency range.

Since then, the development of software formant synthesizers has provided substantially more control over a wider range of acoustic parameters, including nasalization, aspiration, frication, and a variety of vocal source parameters. The greater control and the more veridical modeling of speech production make possible a broader range of experiments. For example, using the Klatt (1980) formant synthesizer, it is possible to modify source characteristics to produce convincing versions of different voice qualities that are indistinguishable from recordings (Klatt and Klatt, 1990). Using these parameters, it has been possible to simulate some of the qualities of pathological voices. This level of control makes formant synthesizers an excellent tool for studying a variety of scientific issues concerning phonetic perception, prosody, and vocal characteristics. However, the requirement of specifying large and complicated sets of acoustic parameters every 5 ms limits the length of utterances that can be practically investigated to syllables or short words.

Articulatory synthesis has not been used as much in perceptual work, although it serves an important role in understanding the relationship between speech production and speech signals. The quantal theory of speech production makes very specific claims about the relationship between variation in physical properties of the vocal tract and the acoustic properties of speech (Stevens, 1972). Thus, the ability to systematically manipulate articulatory structures and assess the acoustic and perceptual consequences is important to understanding both speech production and speech perception. Recent studies have explored how various manners of production may be accounted for in this kind of articulatory synthesis. In addition, the development of a theory of articulatory phonology (Browman and Goldstein, 1986) makes the availability of an articulatory synthesizer an important tool for testing aspects of this theory. However, because of the difficulty of measuring the physical properties of the vocal tract during speech production (compared to measuring acoustic properties using spectrograms or the results of LPC speech analysis), the application of articulatory synthesis remains much more restricted and limited to relatively short utterances.

By contrast with formant synthesis and articulatory synthesis, analytic synthesis based on LPC analysis can be used for research with substantially longer utterances. Words, sentences, and even discourse can be analyzed to extract the source and vocal tract transfer function using LPC analysis. These parameters can then be modified to produce the kinds of variations in phonetic quality or voice quality that are typically investigated using formant synthesis. Furthermore, there is sufficient acoustic–phonetic control to be able to enhance the relevant cues as

a perceptual aid in training. Similarly, analytic synthesis is extremely useful for modifying aspects of the suprasegmental structure of speech. Variation in broad phonotactics, rhythm, and intonation has been varied between English and Japanese sentences to investigate language identification (Ramus and Mehler, 1999). The perception of emotional stress was investigated by resynthesizing utterances varying maximum F0 and the range of F0 (Protopapas and Lieberman, 1997) and variation in mean pitch was controlled for different emotional sentences using LPC resynthesis to investigate the cortical lateralization of processing emotional language and syntax (Luks *et al.*, 1998).

LPC resynthesis allows researchers to model speech stimuli more closely on real utterances and still retain control over source and vocal tract transfer function parameters. Moreover, it allows researchers to prepare much longer utterances as stimuli than would be typical using articulatory or formant synthesizers. However, by comparison, manipulation of acoustic–phonetic cues is not as simple as with formant synthesizers. Thus, analytic synthesis tends to be most useful in research on longer utterances investigating prosody whereas formant synthesis tends to be more useful in synthesizing phonetic structure.

In principle, synthetic speech should be useful in applications wherever human speech would serve as the medium of interaction. Any place where a human operator must interact vocally with someone, to the extent that a computer could perform the human's job, synthetic speech would be useful as the output medium, replacing human speech directly. However, the above difference among synthesizers would seem, on the surface, to constrain the relative utility of synthetic speech for human–computer interactions.

On the one hand, it seems plausible that analytic synthesis in the form of LPC resynthesis could be useful for certain voice response applications. Any situation in which a limited set of prerecorded messages is needed, LPC resynthesis might be considered. Rather than store coded and compressed digital recordings of the messages, an LPC synthesis chip together with stored sets of parameters for the messages would be sufficient for a very efficient voice response system. Spoken messages in cars or elevators or at train stations could be produced by LPC resynthesis. One advantage of this approach is that some aspects of the prosody or voice characteristics could be modified either to produce variation in the messages, to fit the emotional tone to a situation (e.g., in various types of emergencies), or to change the vocal characteristics of the talker. David Sedaris in *Dress your family in corduroy and denim* (2004) tells a story in which he ends up 'programming' his sister's parrot to deliver a personal message as his proxy. In this situation, one could use LPC synthesis to deliver a specific message that is known in advance.

On the other hand, this kind of system cannot provide the flexibility of spoken language that would be needed in applications that typically require a human operator. There are many circumstances in which speech is needed, but the messages could not be prerecorded because there is no way to know ahead of time what will be said. In another story, Sedaris laments that the nematode worms that survived the Columbia space shuttle explosion could not talk; if they could, imagine what we could learn about the accident from real eye witnesses. Who could know ahead of time what they would possibly say? Similarly, in Parkhurst's *The dogs of Babel,* a linguist sets out to teach his dog to talk in order to find out what happened when his wife died. However, it is clear that talking is not just making a certain set of human speech sounds. Talking, as opposed to simply relaying a message, depends on a great deal of knowledge about the structure of language.

As the number of messages becomes large, the time and effort of recording all the messages, carrying out an LPC analysis, and storing the parameters becomes prohibitive. Furthermore, in applications where there can be an unlimited number of messages, as in a reading machine for the blind, it is impossible to have a fixed set of analyzed and stored messages. This kind of voice response system requires a different kind of approach than is represented in any of the speech synthesizers. This point is where the generative power of natural language becomes critical – the ability to produce any arbitrary utterance.

A speech synthesizer can be thought of as the engine that generates phonetic and prosodic signals. Given the right set of source and vocal tract transfer function parameters, a speech synthesizer can generate an utterance or set of utterances. In each synthesizer, there are parameters available that can be used to control syntactic prosody, emotional expression, voicing, nasality, manner and place of articulation, and all the other properties that make up the perceptual structure of speech. However, what is missing is the linguistic structure that ties together these parameters to form a coherent utterance. Speech synthesizers only model the source-filter theory of speech production, but none of the linguistic knowledge that exists in a human talker to drive the production process. Clearly then, in order to produce a voice response system with broader abilities, it is necessary to combine a speech synthesizer into a much more complex system. Those systems are called text-to-speech systems.

Text-to-Speech Systems

A text-to-speech system (TTS) takes unrestricted text and 'reads' the text aloud, or at least renders the text into a speech waveform that can then be transmitted or played to a listener. In this respect, a TTS is more like a human reader than an extemporaneous speaker. While this eliminates the problem of formulating a message into a linguistic surface form, there are still a large number of very specific problems that need to be addressed by engineering and linguistic solutions. While a speech synthesis engine can take time-varying parametric descriptions of speech production (in either articulatory or acoustic terms), these descriptions must be generated from the text input.

Consider some of the basic problems faced by a TTS in reading text. Texts do not consist of phonetic transcriptions with diacritic marks. A TTS typically only has available the information in a text to guide pronunciation and manner of speaking. However, the text must be translated into phonological form. The phonological translation must be converted into phonetic segments and these segments must be rendered into synthesizer parameters. This process is a complex one that consists of a series of stages of translation.

First, the text must be normalized. While some punctuation, such as commas and question marks, periods, and exclamation points can be used as prosodic information for pauses and intonation contours, other punctuation such as single and double quotes and abbreviation periods (as in Dr Jones, where Dr is not the end of the sentence) can cause problems. Should acronyms be spelled out aloud (as in ABC) or pronounced as a word (as in UNESCO)? Numbers have to be converted from Arabic numeric form to phonological form. Some abbreviations have to be decoded in context (as in St Marks as Saint Marks vs. Marks St as Marks Street) and fully expanded phonologically. In reading an e-mail message, as it is received, what should be done about the numerous fields for time, date, sender, and routing that can all appear, with strange punctuation? Similarly, in reading web pages (not specifically marked using a speech markup language), there are numerous text formatting characters that must be ignored or used as directives for a web browser that could provide information for a TTS. Depending on the nature of the text to be read, there are numerous specific issues that need to be addressed before the text can be converted to speech. This first stage of text normalization is therefore necessary to render the text input into a form suitable for conversion to phonological form.

A second stage in text-to-speech systems is a syntactic analysis of the utterance. Even a rudimentary syntactic analysis can be important for determining the pronunciation of some words (an attribute vs. to attribute). Content words typically receive intonational accents whereas functors are unaccented. The overall prosody of the sentence may change depending on the syntactic structure. Some aspects of this kind of analysis may be carried out simply by labeling words based on dictionary lookup and then applying a rudimentary parser. However, there are certain pragmatic solutions that can be applied such as using functors to identify phrase boundaries that can reduce the need for a parser.

In order to read any text, it is critical to change the representation from an orthographic form to a phonological form. Even after transformation of numbers and expansion of abbreviations and the elimination of formatting and irrelevant information, the problem of pronouncing spoken words is not simple. In English, the correspondence between spelling and pronunciation is notoriously poor as exemplified by George Bernard Shaw's spelling of 'fish' as 'ghoti' (think of the pronunciation of these letters in enough, women, and motion) in the *London Times*. Moreover, there are a number of loanwords in any language that may violate normal orthotactics and may be pronounced in unusual ways. Similarly, proper names may be pronounced as they would in the language of origin, or as would be dictated by a local dialect, or by some combination. While loanwords are sufficiently standard to be represented as exceptions that can be looked up in a dictionary, it is much more difficult to list out all the proper names and spelling variants that might be encountered in unrestricted text.

Some text-to-speech systems use a combination of approaches to convert the orthographic form of a word into a phonological form. Irregular words can be stored with their pronunciations in a dictionary. In this case, the pronunciation is simply retrieved. However, if the word is not found in the dictionary, spelling-to-sound rules are often used to generate a pronunciation. The rules to convert spellings to sound patterns for English can be extremely complex, containing hundreds of rules that must be applied in specific order. The development of such rule systems is extremely time and labor intensive requiring a trained linguist to analyze spelling and sound patterns in a language. The MITalk system incorporated a dictionary of 12 000 morphemes and a phrase parser (Klatt, 1987).

An alternative approach to spelling-to-sound conversion was proposed by Sejnowski and Rosenberg (1987), who trained a neural network to associate spelling patterns with pronunciation patterns. Although this approach does not require the

construction of explicit rules by an expert, the performance of this system was not as good as a letter-to-sound rule system (Klatt, 1987). Similarly, Dedina and Nusbaum (1991) proposed using an analogy system to generate pronunciations. If a test item was not found in a dictionary associating spellings and sound patterns, a lattice was constructed pairing the spelling of the word with all possible pronunciations from subparts of the spelling that were found in the dictionary. This procedure would construct a set of alternative pronunciations for each letter in a test word. The final pronunciation would be based on finding a path through the lattice that selected the most probable pronunciations. Although this approach yielded performance that was somewhat less than the rule system of a commercially available TTS, it has the advantage of being automatically generated from a lexicon without expert intervention. Furthermore, local accents can be generated simply by using local pronunciations of items in the dictionary, along with the pronunciations of locally frequent proper names.

The word pronunciations must also be modified to take into account local phonological context effects. For example, phonological assimilation effects between words can change the phonetic features of segments. Elision can drop segments from a pronunciation. Stress patterns can change vowel quality. All of these effects come into play after the canonical pronunciations of words have been determined. In addition, prosodic changes in vowel duration, syllable stress, and phonetic effects of pausing all need to be incorporated into the phonetic representation of the utterance. Finally, the prosodic and phonetic information has to be converted into the parameter form that drives the synthesizer engine.

Just as there are different forms of speech synthesizers, there are different forms of text-to-speech systems. Although there have been efforts to develop text-to-speech systems based on articulatory synthesis, these efforts have not resulted in either widespread adoption of any one system or a successful commercial product. The two types of systems that have been developed most extensively are generally called synthesis-by-rule and concatenative synthesis. In many respects, both types of TTS could be considered quite similar up until the actual synthesis is carried out. The nature of the synthesis process itself does not specifically determine how spelling-to-sound conversion is carried out, or whether or not parsing is used to assign syntactic categories to words. The primary difference is in the nature of the process by which phonetic segments are converted into sound.

In synthesis-by-rule systems (Klatt, 1987), phonetic segments are translated into sound by a sets of rule that incorporate the effects of coarticulation on the acoustic properties of phonetic segments. All the context-conditioned variability in acoustic–phonetic structure (Liberman *et al.*, 1967) must be incorporated into rules. In addition, there need to be rules for the phonetic effects of phonological context and prosodic effects (e.g., lexical contrast). These rules applied to phonetic and prosodic descriptions of an utterance result in the sequence of control parameters that can be used as input to a formant synthesizer such as the cascade/parallel formant synthesizer.

In concatenative synthesis (Klatt, 1987), the basic approach is to assemble an utterance by concatenating adjacent phonetic units like beads on a string. Of course, it has been well understood for decades that, while our subjective impression of speech is a sequence of discrete segments (consonants and vowels), the reality is that the acoustic patterns of these putative segments are highly context dependent, having little or no independent perceptual reality. Thus, it is not really possible to synthesize intelligible or natural speech by editing together a series of spoken words, syllables, or even phonemes. Instead, concatenative synthesis operates at the subphonemic level, taking acoustic segments drawn from the transitions between phonemes as the building blocks of an utterance. The synthesis engine is based on analytic synthesis, typically storing the diphones as LPC parameters and smoothing the parameter sequences prior to resynthesis.

The use of diphones as units explicitly acknowledges the context-conditioned nature of phonetic segments by incorporating at least the adjacent phonetic context. The use of diphones requires a large inventory of such building blocks (e.g., with 40–50 American English phonemes, this inventory would require all the legal transitions between pairs). Furthermore, segment quality could be improved by taking such diphones qualified by a broader window of context (e.g., stressed vs. unstressed). Unlike synthesis-by-rule, the process of assembling an utterance from a phonetic description is much less computationally intensive. Instead of applying complicated rule systems to generate parameter sequences, the appropriate units are simply retrieved, the sequences smoothed, and then the speech resynthesized from the parameters.

Recently, there have been a number of significant improvements in concatenative synthesis. PSOLA (pitch-synchronous overlap-add) uses sampling of subphonemic sequences using pitch-period matched windows. By selecting pitch-synchronous segments, and combining them, using an overlapping window technique, it is possible to achieve more natural variations in segment pitch and duration that previously possible. In addition, the use of multipulse LPC

(MPLPC) has improved the parametric representation of diphone segments, subjectively increasing naturalness and intelligibility. Furthermore, although diphone segments are typically selected carefully by hand with individual screening of segments, new statistical techniques can optimize unit selection and application, thereby automating the process of developing a synthesizer and improving voice modeling (Donovan and Woodland, 1999).

There have also been attempts to develop a text-to-speech system based largely on connectionist models of neural networks. One of these systems was sufficiently developed to be roughly competitive with commercial products (Karaali *et al.*, 1998). This system used two different neural networks to compute the pronunciation of an input text. One network computed context-free pronunciations for words using associations between orthographic forms and phonetic transcriptions. The second network modified the pronunciations given the adjacent pronunciations in the context of the utterance. Two additional networks calculated the acoustic parameters that were used to generate the waveform of the target utterance. One network used the pronunciation patterns as input and generated a sequence of segmental durations. The second network generated vocoder parameters based on the durations and the phonetic sequence. The vocoder parameters were then used to drive a standard mixed-source vocoder to produce the speech. The networks were developed using a standard backpropagation training algorithm to associate two sets of patterns. For example, the spelling-to-sound network associated the spellings and pronunciations of 200 000 words in a lexical database. Similarly, the acoustic–phonetic network was trained to associate narrow phonetic transcriptions of a series of sentences with the vocoder parameters produced by coding the speech of a specific talker. Different networks were needed to specifically encode the talker characteristics of different individuals and the resulting speech was extremely natural (Nusbaum *et al.*, 1995). Although this method offers a different approach that has significant benefits in talker modeling and naturalness, it has not been pursued.

Text-to-Speech Synthesis in Languages Other Than English

The complexity of text-to-speech conversion varies considerably depending on the linguistic structures of a specific language. Grapheme-to-phoneme conversion is greatly simplified when dealing with languages characterized by a relatively shallow orthography that exhibit a high spelling-to-sound correspondence such as Italian or Finnish. The conversion task is also simpler in languages that use syllabic script, where each written unit represents a syllable, such as Japanese *kana*. On the other hand, this task is more complex in languages with deep orthography, such as French, or in languages that use a consonant script where vowels are not represented in the writing system, such as Arabic (Arabic, Standard) and Hebrew. Although the phonetic description that is the final product of the conversion process can be represented by the language independent International Phonetic Alphabet (IPA), most computers require a representation based on ASCII characters. Phonetic sets such as the SAMPA, originally designed for European Languages, or the ARPAbet, designed for American English, use computer-friendly ASCII characters but are less powerful and do not cover all languages.

Currently, multilingual commercial TTS systems are available for a large number of languages, including U.S. English, U.K. English, Arabic, Chinese (Mandarin and Min-Nan), Czech, Danish, Dutch, Finnish, French, German (standard), Icelandic, Italian, Japanese, Norwegian (Bokmaal), Portuguese, Spanish, Swedish, and Turkish. Commercial systems include both formant-based synthesizers, containing language-specific rules, and concatenation-based synthesizers containing language-specific databases. Noncommercial multilingual TTS systems have also been developed, although they are available for a smaller number of languages such as English (American and British), German, Japanese and Spanish.

One major development project is the MBROLA system, initiated by the TCTS Lab of the Faculté Polytechnique de Mons in Belgium, aimed at developing a noncommercial, freely available multilingual speech synthesizer. The MBROLA synthesizer is based on diphone concatenation and free databases for different languages are currently available or under development including, but not limited to, Estonian, Hindi, Hebrew, Croatian (Serbo-Croatian), and Telugu, although some are still under development. MBROLA takes as input a list of phonemes and prosodic information. Thus, MBROLA represents an intermediate system between an analytic synthesizer and a full concatenative TTS, although commercial and noncommercial TTS systems that are compatible with MBROLA are available.

In addition to multilingual synthesis systems, some efforts have been undertaken to construct polyglot synthesis systems. Although multilingual synthesis systems can produce speech in more than one language, they are not usually able to switch from one language to another within the same sentence. In contrast, polyglot synthesis systems are designed so they can synthesize mixed-language texts. One benefit of polyglot synthesis systems is that they are able

to handle loanwords and absorbed foreign words that may differ in prosody and pronunciation from original language words.

Applications of Text-to-Speech Systems

We use speech for so many interactions on a daily basis; the major limiting factor in the application of text-to-speech systems is the quality of the speech and the nature of the interface to the system. The easiest form of application for a TTS is where there exists a collection of information in text form and the primary nature of the interaction with the data is simply to have it read aloud. Indeed, the idea of a reading machine for the blind was one of the earliest motivations for a text-to-speech system, and one of the more successful early commercial products developed, the Kurzweil Reading Machine, was designed for that purpose. In any circumstance where a blind person wants access to text information, a text-to-speech system provides a significant benefit. For example, blind programmers used the very low cost Votrax Type-'n-Talk as a substitute for a video terminal, in spite of the low quality of the speech, simply due to the motivation and desire to have an alternative functional display system. A direct extension of this specific application is to provide reading services to sighted people in circumstances where text data cannot be easily displayed. Thus, text-to-speech systems have functioned as display systems for e-mail and news over voice-only telephones. Wherever there is text data and no way to display it visually, a telephone becomes a display system if a text-to-speech system is available.

However, when the input to a TTS consists solely of text, it is not always possible to determine the correct pronunciation of words, or to control the prosody of the speech output. A more fully specified input that makes semantic and pragmatic information available for synthesis can greatly facilitate prosody generation. To some extent, this specification can be achieved by the use of markup languages that use specific tags to control aspects of the synthesized speech such as pronunciation, pitch, rate, emphasis, or pauses. The first attempt to develop a TTS markup language is the SSML (Speech Synthesis Markup Language) developed at the University of Edinburgh (Taylor and Isard, 1996). Recent efforts include the SSML specification developed by the World Wide Web consortium and the SABLE markup language, developed by a consortium involving Edinburgh University, Bell Laboratories, British Telecom, AT&T, Sun Microsystems, and Carnegie Mellon University. In addition to facilitating the control of pronunciation and prosody generation, the use of a standard markup language enables the portability of annotation schemes from one TTS system to another instead of annotation schemes that are platform specific. Speech synthesis markup languages can also serve as the interface between a natural language generator component (NLG) and a synthesizer in concept-to-speech systems (see below), which may become more important when speech synthesis is used in a dialogue system rather than as an audio text-display device.

The next level of application is in circumstances where a person currently interacts with a human operator. Whenever speech interactions take place, there is the potential to replace the human operator with a text-to-speech system, a speech recognition device, and a computer. A variety of telecommunication services such as directory assistance and reverse directory have made use of concatenative synthesis to reduce or eliminate the demands on a human operator's time. For example, as soon as a number is located, speech synthesis can provide a response instead of the human. Moreover, service requests and a variety of orders and transactions over the telephone present target applications for synthetic speech. For years, AT&T researchers have used airline reservations as a model system for automated speech interaction. The combination of high-quality speech recognition with text-to-speech synthesis turns any telephone into a computer terminal for a wide range of applications from text entry and editing to command and control of equipment such as an electrical power plant.

By extension, speech recognition and text-to-speech systems provide important utility in situations where a person's eyes and hands are busy. In a car, a system that reads directions as you are driving, based on a database and global positioning system, is a very useful substitute for a friend in the car with a map. Similarly, there are a number of military applications in which text-to-speech systems could provide a great deal of information over a voice channel about logistical or tactical conditions. In much the same way, text-to-speech systems could provide realtime information to surgeons about patient status or in response to various medical queries.

For people who are unable to speak, text-to-speech systems offer the possibility of a vocal prosthesis. In 1982, a Nova TV program showed Dick Boydell, a man with cerebral palsy – unable to speak more than 'yes' or 'no' for 30 years – use a text-to-speech system to talk and order a pizza over the telephone by himself. Stephen Hawking, the physicist, used DECtalk, developed by Dennis Klatt and the Digital Equipment Corporation, as his voice, as did Klatt himself toward the end of his life. Text-to-speech systems provide an ability to communicate with the

world using speech, but have significant limitations for this purpose. First, the entry of messages is not at all simple, even with full motor ability and a keyboard. While just having the ability to speak is better than the alternative, it slows down the communicative process to have to type in messages. And in some cases, the disease that impairs speaking also impairs typing, requiring alternative means of message entry. Second, people with a need for voice prosthesis express concern over the limited voice quality typically available. Although with concatenative synthesis (and using statistical modeling techniques), it is now possible to more closely match the vocal characteristics of a synthesizer to a particular person, it is seldom done. People think of a voice as an extension of themselves; for example, most women would not want a masculine voice. Moreover, the prosodic variability of most text-to-speech systems is extremely limited. While questions and statements may be prosodically marked, more subtle expressions and emotion are not.

Text-to-speech systems have also been applied in educational settings. Certainly a talking computer is a potential tutor, able to provide information, guidance, and feedback to any student. In this kind of application, the computer can interact with students more like a human teacher using speech. Synthetic speech has also been used for teaching a second language. Commercial products have been developed specifically for language instruction, giving feedback to a nonnative speaker and providing model utterances to be copied. By this model application, text-to-speech systems are now being explored as a possible therapeutic training aid for people with Broca's aphasia. The primary predictor of the success of poststroke therapy is the amount of therapeutic work a patient does at home. A computer avatar therapist who speaks with a TTS can be available at any and all times for a patient at home, increasing the amount of possible therapeutic work.

Text-to-speech systems also been applied to entertainment. The first song sung by a computer was 'Daisy, Daisy,' synthesized in 1961 by Kelly and Lochbaum at the Bell Laboratories. This first attempt was later alluded to in the Stanley Kubrick's movie *2001: a space odyssey* (1968). Just before he is disconnected, as he is regressing, the ship's computer HAL 9000 begins to sing the same song.

Uses of singing voice synthesis include computer games, musical instruction, composition, and as a musicological research tool. Various systems were designed specifically for singing voice synthesis. These systems utilize the same basic methods used for speech synthesis such as articulatory synthesis, concatenative synthesis, and formant-based synthesis. The input to singing voice synthesis systems typically consists of a MIDI file and a text containing the lyrics of the songs to be synthesized. Typically singing voice synthesis systems allow some control over parameters such as vibrato, pitch band, and volume. Singing usually employs a wider range of fundamental frequencies and a wider pitch range than employed in speech. Singing voice synthesis may differ from speech synthesis in the importance of parameters such as these that contribute to the naturalness, expressiveness, and musical quality of the output relative to overall intelligibility.

Evaluation of Synthetic Speech

Although naturalness and intelligibility have improved significantly in recent years, synthetic speech is still not equivalent to natural speech. Perception and comprehension of synthetic speech is still worse than natural speech (*see* **Speech Synthesis: Perception and Comprehension**), and it degrades faster under adverse listening conditions (e.g., noise, distraction, divided attention). There are a number of issues that need to be considered in evaluating the performance of a speech synthesizer or text-to-speech system. At the very least, the quality of synthetic speech can differ in segmental intelligibility, prosody, and naturalness. However none of these is simply determined by the raw signal quality of the system. This quality is certainly one component of the overall performance of a text-to-speech system. Nusbaum and Pisoni (1985) argued that besides signal quality, performance of a text-to-speech system depends on the demands and complexity of the task in which the speech is used, the cognitive limitations of the person using the system, the experience and training of the user, and the linguistic structure and complexity of the message.

When tasks are demanding, the ability to understand synthetic speech is adversely affected. To take an extreme example, Navy pilots, when trying to land on an aircraft carrier while their plane is on fire, reported they did not hear any of the warning sounds or messages. The more that a task demands attention, the harder it will be to understand speech. Conversely, the more experience a listener has with a particular text-to-speech system, the higher the intelligibility of the speech. Blind programmers who routinely used the Votrax Type-'n-Talk, a relatively low-intelligibility synthesizer, reported that the speech quality improved substantially. Indeed, Schwab *et al.* (1985) found that moderate amounts of training produced huge gains in intelligibility that lasted for six months and extended to all the speech produced by the synthesizer. As linguistic structure becomes more complex, the difficulty of comprehension will interact

with segmental intelligibility. But the more redundant the discourse, the easier it will be to understand synthetic speech. However, as synthetic speech becomes used in more sophisticated applications, it will become important to go beyond measures of intelligibility, comprehension, and naturalness and evaluate more social aspects of our perception of synthetic speech.

Challenges for the Future of Synthetic Speech

Synthetic speech today still does not meet the test of the voice of the HAL 9000 computer. But the largest challenges are probably not in the realm of improving the intelligibility or naturalness of synthetic speech. The quality of synthetic speech is nearing the level of natural speech. The challenges are perhaps greatest in the very nature of a text-to-speech system: These systems convert text into a phonological structure that is produced as speech, but these systems do not read. Without real comprehension and without the ability to productively generate language, there will be inherent limitations on the nature of synthetic speech. A segment of the NPR radio program *The Next Big Thing* (NPR, 2003) hit on exactly this limitation: there is a fundamental lack of humanity in the expressiveness of synthetic speech that gives it a mechanical characteristic. Two areas of research offer the possibility of improving this aspect of synthetic speech, concept-to-speech synthesis and emotional synthesis.

Rather than starting with a text as input, as in standard TTS systems, concept-to-speech (CTS) synthesis systems start from semantic/conceptual information generated by a natural language generation system. Speech generation is done either by a complete synthesis or by slot and filler synthesis where a carrier phrase contains slots that can be replaced by a set of prerecorded words. This method is useful for information systems in which the information to be synthesized is generated by the system. In these cases, the system 'knows' the meaning of the information to be synthesized and can avoid the ambiguities inherent in a textual representation. CTS was first proposed as a synthesis method by Young and Fallside (1979). In the last decade there have also been attempts to incorporate more abstract levels of representation such as discourse structure and communicative context into speech production systems. For example the communicative context-to-speech synthesis proposed by Teich *et al.* (1996) that involves a specification of speech functions (statement, question etc.), pragmatic function, and speaker attitude.

Indeed, human speech is not used only for communicating linguistic lexical or propositional content. Vocal characteristics such as pitch, timing, and voice quality (for example, breathy or resonant) can convey a great deal of information about emotion (Murray and Arnott, 1993). The prevalence of emoticons in e-mail messages and other Internet-based communication program attests to the importance of such emotional information. Emotional speech synthesis is also important for the use of synthetic speech as prosthesis for voice-disabled individuals that need to rely on synthetic speech for conveying the same range of information conveyed by human speech. Finally, research has shown that individuals display a range of social responses towards computers (Nass and Moon, 2000). Users' responses to human–machine interfaces may depend not only on how intelligible the speech is, but also on the emotion or other personality characteristics displayed by the speech. Based on research on the acoustic correlates of emotion in human speech, one can specify acoustic parameters correlating with basic emotional categories such as anger, joy, sadness, disgust, or surprise. The effects of emotion on human speech can then be imitated in the synthesized speech. Cahn (1990) has shown that recognizable discrete affect categories can indeed be generated in synthetic speech. There have also been attempts to synthesize emotional speech using a concatenation-based synthesis using diphones from different emotional categories.

As in evaluating the intelligibility of speech, there is no one obvious method of evaluating emotional speech synthesis. Most studies have used a forced choice task in which listeners were asked to determine the emotion displayed out of several alternatives. The alternatives presented and the specific emotions synthesized may affect listeners' responses and lead to results that are different from spontaneous perception of vocal emotion. Other studies have also used ratings of naturalness, believability, and intensity in order to evaluate emotion synthesis. In addition, few efforts have been made toward synthesizing and evaluating variations within the same emotional category (for example, hot or cold anger). In addition to progress in emotional speech synthesis, it will be a challenge for the future to develop systems that are able to generate synthetic speech displaying personality characteristics usually conveyed by human vocal characteristics. Like vocal characteristics associated with emotion, these contribute to the naturalness of speech and may be important for human computer interaction.

Synthetic speech is currently used in a wide and ever widening set of applications, from basic research in linguistics and psycholinguistics to second language teaching and stroke recovery. Many of the promises of the first days of speech synthesis have been realized

in terms of reading machines for the blind and automated voice response systems. However, there is still a long way to go in developing systems that can truly substitute for a human interlocutor.

Speech Synthesis, Perception and Comprehension of

S J Winters and D B Pisoni, Indiana University, Bloomington, IN, USA

© 2006 Elsevier Ltd. All rights reserved.

When research on the perception of synthetic speech began in the early 1970s, speech scientists were primarily interested in evaluating its segmental intelligibility with respect to natural speech. These early studies were done with an eye toward improving the quality of synthetic speech for use in practical applications, such as reading machines for the blind or voice output communication devices. For instance, Nye and Gaitenby (1973) not only tested the intelligibility of synthetic speech against natural speech but also identified the synthetic speech sounds that were difficult for listeners to perceive correctly. They wanted to identify these sounds so that researchers could improve their intelligibility by refining the text-to-speech algorithms that produced them. In this way, speech scientists hoped that the knowledge gained from perceptual research would help them elevate the overall intelligibility of synthetic speech to the same level as natural speech.

Following Nye and Gaitenby's pioneering assessment work, the question of why synthetic speech was more difficult to perceive than natural speech took on an increasingly important role in research on the perception of synthetic speech. Researchers wanted to know if synthetic speech lacked certain characteristics that might be crucial to the perception of natural speech. Establishing what these characteristics might be required knowing more about the perception of synthetic speech than just measuring its segmental intelligibility. Pisoni (1981), for instance, suggested that future research on synthetic speech perception should be carried out in the 10 areas listed in **Table 1**.

Table 1 Needed research on the perception of synthetic speech

9. Generalization to novel utterances
10. Effects of message set size

Adapted from Pisoni (1981).

All of these lines of research have been pursued, to varying extents, in the years following Pisoni (1981). The results of this work have shown consistent differences in perception between natural and synthetic speech at every level of analysis (Duffy and Pisoni, 1992; Pisoni, 1997a; Pisoni *et al.*, 1985). These perceptual differences appear to be based primarily on the acoustic–phonetic characteristics of the two types of speech signals. This conclusion is drawn in large part on the basis of research on the perception of synthetic speech produced by rule (Pisoni, 1997a). Algorithms that produce synthetic speech by rule take an orthographic string of letters as input and convert them into speech output by using a set of text-to-speech conversion rules. Using rules to produce speech in this way yields a speech signal that lacks much of the fine-grained acoustic–phonetic variability inherent in natural speech. Furthermore, synthetic speech produced by rule provides only minimal cues to particular segments or sound contrasts. Text-to-speech conversion rules also tend to use highly simplified coarticulation sequences between individual segments, and they often lack appropriate or natural-sounding sentential prosody. The manifest difficulties of perceiving speech with these acoustic–phonetic characteristics have thus led researchers to conclude that, normally, speech perception not only relies on redundant cues to particular segments but also makes use of the natural acoustic–phonetic variability inherent in the speech signal.

Figure 1 Error rates for word recognition in open- and closed-format MRT, by synthetic voice type. Adapted with permission from Logan J S, Greene B G & Pisoni D B (1989). 'Segmental intelligibility of synthetic speech produced by rule.' *Journal of the Acoustical Society of America 86*, 566–581.

Redundancy and variability in the signal are therefore fundamentally important to the process of speech perception and not just 'noise' that needs to be filtered away through some kind of perceptual normalization process (Pisoni, 1997b).

This article reviews evidence from studies on the perception of synthetic speech that has led researchers to draw these conclusions about normal speech perception. The article is organized around seven empirical findings. These detail the various distinctions that have been found to exist between the perception of natural and synthetic speech, from the earliest intelligibility studies to recent studies on comprehension, perceptual learning, alternative groups of listeners, naturalness, and prosody. The final section concludes with suggestions for potentially fruitful areas of future research in the context of the rapidly changing world of speech synthesis technology.

Finding 1: Synthetic Speech Is Less Intelligible Than Natural Speech

The Modified Rhyme Test

Extensive evidence showing that synthetic speech is less intelligible than natural speech has come from studies that have used the Modified Rhyme Test (MRT) to assess segmental intelligibility (Fairbanks, 1958). The MRT presents listeners with a spoken word and then requires them to select the word they have heard from a set of six response alternatives, all of which differ by only one phoneme. Nye and Gaitenby (1973) first used the MRT to assess the segmental intelligibility of synthetic speech produced by the Haskins Parallel Formant Resonance Synthesizer (Mattingly, 1968). Their study established that listeners made more errors on the MRT for synthetic speech stimuli (7.6%) than they did for natural speech stimuli (2.7%). The MRT has yielded similar results for a wide variety of different speech synthesizers (Greene *et al.*, 1984; Hustad *et al.*, 1998; Koul and Allen, 1993; Logan *et al.*, 1989; Mitchell and Atkins, 1988; Pisoni, 1987; Pisoni and Hunnicutt, 1980; Pisoni *et al.*, 1985).

As early as Nye and Gaitenby (1973), however, it was noted that there are fundamental problems in using the MRT as an evaluative tool to assess synthetic speech intelligibility. Its closed-response set provides a limited number of possible phonemic confusions, and it also does not present all phonemes in equal proportions in the test stimuli. Another problem with the MRT is that it is simply too easy; ceiling effects are frequently obtained when natural or high-quality synthetic stimuli are presented under clear listening conditions. One way to address this problem with the MRT is to eliminate the forced-choice response task. In this 'open-response format' of the MRT, listeners simply respond to each particular word by writing down whatever they think they heard.

Logan *et al.* (1989) used both the 'closed-set' and 'open-set' response formats of the MRT to test the

Figure 2 Percentage correct word recognition in open- and closed-format MRT, by voice type and signal-to-noise (S/N) ratio. Adapted with permission from Pisoni D B & Koen E (1981). 'Some comparisons of intelligibility of synthetic and natural speech at different speech-to-noise ratios.' In *Research on speech perception progress report No. 7.* Bloomington, IN: Speech Research Laboratory, Indiana University. 234–254.

segmental intelligibility of 10 different synthesis systems. Figure 1 shows the percentages of errors that Logan *et al.*'s listeners made in identifying words produced by all of these systems in both formats of the MRT. Logan *et al.* also tested the intelligibility of naturally produced items in the same way. Listener error rates were higher for all versions of synthetic speech than for natural speech; they were also higher in the open-set format than in the closed-set format. Logan *et al.*'s results also revealed that the intelligibility of synthetic speech depends on the type of synthesizer being used to produce the speech. The low error rate observed for DECTalk ($\approx 5\%$), for instance, approximated that of natural speech, whereas the error rate for the Echo synthesizer was greater than 30% in the same response format.

Intelligibility of Synthetic Speech in Noise

Although the best forms of synthetic speech may approximate the segmental intelligibility of natural speech under clear listening conditions, their intelligibility decreases substantially in noise. Pisoni and Koen (1981) first tested the effects of noise on synthetic speech intelligibility with an MRT study in which they played natural and synthetic (MITalk) speech stimuli to listeners in various levels of white noise. Figure 2 shows the percentages of words their listeners correctly identified in the different listening conditions. Their results revealed an interaction between the level of noise and voice type: overall, natural speech was more intelligible than synthetic speech, but increasing the level of noise had a significantly greater detrimental effect on the intelligibility of synthetic speech than it had on the intelligibility of natural speech.

Clark (1983) followed up on Pisoni and Koen's (1981) findings by investigating whether noisy listening conditions affected the intelligibility of some synthetic speech sounds more than others. Clark found that although the intelligibility of synthetic vowels was surprisingly robust in noise, the intelligibility of synthetic consonants – especially stops and fricatives – was seriously degraded by noisy listening conditions. However, Clark found that the rank-ordering of the intelligibility of natural and synthetic consonants was the same in noisy listening conditions. Clark therefore concluded that synthetic speech might be considered a 'degraded' form of natural speech, with cues to individual segments that were simply not as perceptually distinctive as their natural counterparts.

However, Nusbaum *et al.* (1984) found that listeners not only had more difficulty identifying synthetic consonants in noise but also often misidentified synthetic consonants in ways that they never misidentified natural consonants. Even in listening to high-quality DECTalk synthesis, for instance, listeners often misidentified /r/ as /b/ – a perceptual confusion that never occurred for natural speech tokens of /r/. Nusbaum *et al.* therefore suggested that some synthetic speech cues could be misleading to the listener as well as being degraded versions of their natural counterparts.

Recent investigations of the perception of synthetic speech in noise have used multitalker 'babble' rather than white noise. Koul and Allen (1993), for instance, incorporated multitalker noise into an open-response version of the MRT, using both natural and DECTalk voices. They found that the intelligibility of synthetic speech deteriorated more rapidly than natural speech under decreasing signal-to-noise ratios. They also found similar perceptual confusions for both natural and synthetic segments – except for the segment /h/, which was often misidentified in DECTalk but rarely confused with other segments in natural speech. Koul and Allen suggested that the babble noise might influence the perception of synthetic speech in this unique way because its acoustic energy is primarily concentrated in lower frequencies rather than evenly spread across the frequency spectrum, as in white noise.

Perception of Formant vs. Concatenative Synthesis

In recent years, speech synthesis technology has relied increasingly on 'concatenative' synthesis techniques (Atal and Hanauer, 1971; Dutoit and Leich, 1993; Moulines and Charpentier, 1990). Concatenative synthesis uses an actual human voice as its source rather than the output of an electronic model of the human vocal tract. Concatenative synthesis algorithms operate by joining together small portions of recorded human speech – typically 'diphone'-sized units, extending from the midpoint of one phoneme to the midpoint of the next – into specified phonemic strings. Impressionistically, synthetic speech produced in this way sounds more natural to listeners than synthetic speech produced by rule; however, the available research has not confirmed that concatenative synthesis is more natural sounding or even more intelligible than rule-based 'formant' synthesis.

Studies assessing the segmental intelligibility of early forms of concatenative (diphone) synthesis, such as RealVoice and SmoothTalker, indicated that they were less intelligible than high-quality formant synthesis systems, such as DECTalk (Logan *et al.*, 1989). Recent diphone-based synthesizers, however, have nearly matched DECTalk in intelligibility. Rupprecht *et al.* (1995), for instance, measured the intelligibility of DECTalk and the diphone-based synthesizer MacinTalk Pro by playing listeners sentences from the Speech Perception in Noise (SPIN) test (Kalikow *et al.*, 1977), as produced by both voices, and then asking the listeners to identify the last word in each sentence. Rupprecht *et al.* found no significant differences in the number of DECTalk and MacinTalk Pro items that listeners correctly identified in this task. However, Hustad *et al.* (1998) also assessed the intelligibility of DECTalk and MacinTalk Pro synthesis in an open-response format MRT and found a slight but significant advantage in intelligibility for the DECTalk voice. They suggested that Rupprecht *et al.*'s failure to find such a difference in their earlier study may have been the result of their listeners relying on higher-level syntactic and semantic cues to identify words in the SPIN sentences.

Venkatagiri (2003) measured the segmental intelligibility of four different concatenative and formant-based speech synthesizers by playing their productions of MRT words in neutral sentence contexts to listeners in two different levels of multitalker babble noise. Venkatagiri found that the synthesis systems that used concatenative synthesis (NextGen and Festival) were significantly more intelligible than the one that used formant-based synthesis (ViaVoice). All these systems were, in turn, significantly more intelligible than FlexVoice, which used a combination of formant and concatenative synthesis. Formant-based synthesizers also outperformed the concatenative synthesizers on vowel intelligibility, whereas the concatenative synthesizers produced more highly intelligible consonant sounds. This pattern of results suggested a trade-off between vowel and consonant intelligibility, depending on the type of synthesis algorithm used. The relatively poor performance of the FlexVoice synthesizer, which combined the formant and concatenative approaches, also indicated that speech synthesis technology had not yet advanced to the point at which it is possible to combine the best perceptual aspects of both production algorithms into one system.

Finding 2: Perception of Synthetic Speech Requires More Cognitive Resources

Lexical Decision

Studies investigating the time course of synthetic speech processing have consistently shown that the poor segmental intelligibility of synthetic speech forces listeners to engage more cognitive resources in order to perceive it correctly. In Pisoni (1981), for instance, listeners performed a speeded lexical decision task in which they heard both naturally and synthetically (MITalk) produced words (e.g., 'colored') and nonwords (e.g., 'coobered'). Pisoni found that listeners consistently took more time to execute this task when they heard synthetic stimuli than when they heard natural stimuli. Since this effect did not interact with the lexical status of the stimulus, listeners evidently had to apply more cognitive resources to the perception of the acoustic–phonetic

surface structure of synthetic strings prior to any higher-level lexical or semantic processing.t

Word Recognition

Manous and Pisoni (1984) found that synthetic speech puts increased cognitive demands on listeners in a word recognition task. Using the gating paradigm developed by Grosjean (1980), Manous and Pisoni presented listeners with synthetically (DECTalk) and naturally produced sentences in which the duration of the final word increased by 50 ms on each successive trial. Thus, listeners heard the first 50 ms of the word on the first trial, the first 100 ms of the word on the second trial, and so on. The authors found that listeners needed to hear, on average, 361 ms of naturally produced words before they could reliably identify them, whereas they needed to hear 417 ms of synthetically produced words before they could identify them with the same level of accuracy. Manous and Pisoni attributed this difference in performance to the poor segmental intelligibility of synthetic speech. Since DECTalk provided less intelligible cues to individual segments than natural speech, listeners needed to hear more of the synthetic speech signal before they could reliably identify whole words.t

Word Recall

Luce (1981) suggested that the difficulty of perceiving the acoustic–phonetic structure of synthetic speech may actually make the subsequent recall of synthetically produced words easier than the recall of naturally produced words. Luce tested this hypothesis by playing listeners passages spoken in both MITalk and a natural voice. After hearing these passages, the listeners answered questions about whether particular words, propositions, or themes had appeared in them. Luce found that the recall of individual words from the synthetic passages was better than the recall of words from the natural passages, even though the recall of more abstract propositions and themes was better when they had been produced in a natural voice. Since recall of synthetic speech improved only at the lexical level, Luce hypothesized that the need to expend greater cognitive effort in word recognition – due to the poor intelligibility of synthetic speech – created more robust representations of synthetic words in memory.

Luce's (1981) initial findings on the perception of connected speech, however, conflicted with the results of subsequent studies on the recall of lists of synthetic words. Luce *et al.* (1983), for instance, found that listeners could recall more items from unordered lists of natural words than they could from unordered lists of synthetic words. The same effect emerged when Luce *et al.* asked their listeners to recall the same lists after they had first memorized a list of digits. Listeners' recall of the digit lists was also worse when they were presented before synthetic word lists. This interaction indicated that both digit and word recall shared the same, limited-capacity store of cognitive processing resources, and that the storage and retention of synthetic words absorbed more of these processing resources than the storage and retention of natural words.

Luce *et al.* (1983) also investigated the serial recall of natural and synthetic word lists. In a serial recall task, listeners must memorize a list of words and then recall them in the correct order. Luce *et al.* found that listeners were best at recalling words that appeared early and late in ordered lists. These 'recency' and 'primacy' effects interacted with the type of voice used; overall, the recall of natural words was better than the recall of synthetic words, but this advantage was significantly larger for words appearing early in the lists than it was for words appearing late. Luce *et al.* hypothesized that this interaction occurred because the storage of synthetic words required more processing and memory resources than the storage of natural words. Late items in the synthetic lists might therefore appropriate memory resources that would otherwise be reserved for the storage of early items. The recall of early synthetic items would then be disadvantaged not only by the fact that they required more memory resources than early natural items but also by the fact that subsequent items in the synthetic lists required more memory resources as well.

Luce and Pisoni (1983) tested these hypotheses by asking listeners to recall mixed lists of words in which five natural words were followed by five synthetic words (and vice versa). The authors only included synthetic words in these lists that closely matched their natural counterparts in segmental intelligibility. They hypothesized that the synthetic words that appeared late in these lists should adversely affect the recall of the natural words that appeared earlier in the same lists. They found that the listeners did recall natural words better than synthetic words but only in positions 2, 3, and 5 of the 10-item lists. Since such differences in recall were found using lists of highly intelligible synthetic words – whose acoustic-phonetic interpretation required minimal amounts of extra cognitive effort – this finding suggested that the processing of synthetic speech at more abstract levels might also require more cognitive processing resources than natural speech.

Finding 3: Perception of Synthetic Speech Interacts with Higher-Level Linguistic Structures

Perception of Words in Sentences and in Isolation

Listeners also appear to compensate for the poor segmental intelligibility of synthetic speech by relying on any available higher-level linguistic information to help them perceive synthetic speech correctly. Hoover *et al.* (1987) demonstrated that the perception of synthetic words in sentences is significantly better than the perception of synthetic words in isolation. They constructed sentences in which the final word could be guessed, on the basis of the preceding words in the sentence, with either high or low probability. They then recorded these sentences – along with the final words, in isolation – in a natural voice and with the Echo II and Votrax synthesizers. The words and sentences were presented to listeners, who were asked to repeat what they heard. Table 2 shows the correct repetition scores for all sentences and words by voice type.

In general, repetition accuracy was higher for sentences than it was for isolated words. This effect was even more pronounced for the high-probability sentences than it was for the low-probability sentences. The percentages of correct repetitions in Hoover *et al.* (1987) indicate that listeners can extract far more information out of linguistic context and sentence structure than they can reliably extract from the synthetic speech signal alone.

Table 2 Percentage of words correctly repeated, by voice type and presentation context

	Single words (%)	*Low-probability sentences (%)*	*High-probability sentences (%)*
Votrax	21.9	35.3	87.8
Echo II	19.5	23.8	77.3
Natural	99.9	100	100

Adapted from Hoover *et al.* (1987).

Although higher-level linguistic information may be particularly helpful to a listener who is attempting to perceive poor-quality synthetic speech, such as Votrax or Echo II synthesis, it may also assist in the perception of high-quality synthetic speech. Mirenda and Beukelman (1987) tested the perception of synthetic words and sentences that were produced by the highly intelligible DECTalk synthesizer and found that correct word identification rates increased from 78% in isolated word contexts to 96.7% in sentences. The percentage correct for sentence stimuli approximated performance on natural speech versions of the same tokens, which was near ceiling at 99.3% correct. In a follow-up study, Mirenda and Beukelman (1990) expanded the range of synthesizers used to produce the sentence and word tokens and found, again, that the sentential contexts improved the intelligibility of all synthetic voices. The best synthesizer in the second study, SmoothTalker 3.0, was a diphone-based system, which approximated the intelligibility levels of natural speech in both isolated word and sentential contexts.

Semantically Anomalous Sentences

Higher-level linguistic information may, in certain cases, actually make the perception of synthetic speech more difficult. Nye and Gaitenby (1974) studied the perception of 'semantically anomalous' sentences, which lack semantic coherence and predictability (e.g., 'The safe meat caught the shade'). They found that correct identification rates were much lower for synthetic words in these sentences (78%) than they were for synthetic words presented in isolation in the MRT (92%). This effect was also proportionally greater for synthetic speech than it was for natural speech; listeners correctly identified 95% of naturally produced words in semantically anomalous sentences and 97% of naturally produced

Figure 3 Percentage of synthetic and natural words correctly identified, by duration of target stimulus in congruent and neutral sentential contexts. Adapted with permission from Duffy S A & Pisoni D B (1991). 'Effects of sentence context on the signal duration required to identify natural and synthetic words.' In *Research on speech perception progress report No. 17*. Bloomington, IN: Speech Research Laboratory, Indiana University. 341–354.

words in the MRT. Nye and Gaitenby attributed this effect to the difficulty listeners might have in parsing individual words out of a longer string of words, but they also pointed out that higher-level sentential information might bias listeners toward expecting to hear words that fit into the sentence's semantic context and thus make semantically incoherent words more difficult to recognize, especially if they were produced synthetically.

Gating in Sentences

Duffy and Pisoni (1991) noted that the correct identification rates for both natural and DECTalk speech in Mirenda and Beukelman's (1987) sentence transcription study were close to ceiling levels of performance. They investigated whether higher-level semantic information would affect the high intelligibility levels of these two kinds of speech equally in a gating paradigm. Duffy and Pisoni presented sentences to listeners in which the final, gated words were either in a congruent (e.g., 'The soldiers flew in the helicopter') or a neutral (e.g., 'The people were near the helicopter') context; these sentences were produced in either synthetic (DECTalk) or natural speech.

Figure 3 shows the percentage of correct identifications of the final words, as produced by both natural and synthetic voices, for each presentation of those words at the various gating durations. On average, listeners needed to hear 68 ms more of the synthetic words than the natural words before they could reliably identify them. The effect of voice type interacted significantly with the type of sentence context: Listeners needed to hear 212 ms more of the synthetic words when they appeared in the 'neutral' contexts than when they appeared in the 'congruent' contexts before they could reliably identify them. These results indicated that listeners not only required more acoustic–phonetic information from synthetic speech before they could reliably identify words but also that they drew more heavily on higher-level semantic information in order to compensate for the difficulties incurred in processing the impoverished acoustic–phonetic structure of synthetic speech.

Finding 4: Synthetic Speech Is More Difficult to Comprehend Than Natural Speech

Postperceptual Tests of Comprehension

Studies on the comprehension of synthetic speech have yielded different results depending on whether they have investigated the 'products' or the 'process' of comprehension. Nye *et al.* (1975) tested comprehension by asking listeners to answer multiple-choice questions that were based on a series of passages they had heard produced by either a natural voice or a synthetic voice. They found that the proportion of questions the listeners answered correctly did not vary according to the type of speech they heard. Assessing the products of comprehension with this postperceptual measure did not, therefore, reveal significant differences in comprehension between synthetic and natural speech. However, listeners did take a significantly longer amount of time to answer the multiple-choice questions when they heard the synthetic voice than when they heard the natural voice. Thus, using an on-line measure to gauge the process of comprehension did reveal substantial differences in processing time between the comprehension of natural and synthetic speech.

Subsequent studies using postperceptual measures of synthetic speech comprehension have yielded a similar pattern of results. Ingemann (1978) replicated Nye *et al.*'s (1975) methodology using a more advanced speech synthesizer and found no differences between natural and synthetic voices in the number of multiple-choice questions that listeners answered correctly. Pisoni and Hunnicutt (1980) also assessed comprehension by having listeners answer multiple-choice questions based on passages that they had read, heard spoken by a human voice, or heard spoken by the MITalk text-to-speech system. Pisoni and Hunnicutt found that listeners answered the most questions correctly if they had read the passages, but that the level of their performance did not differ between the natural voice and MITalk conditions.

On-Line Measures: Sentence Verification

Clear differences in comprehension between natural and synthetic speech ultimately emerged with the development of more sophisticated on-line measures of the process of speech comprehension. Manous *et al.* (1985) used a sentence verification paradigm to study the comprehension of synthetic speech. In this paradigm, listeners hear a short declarative sentence (e.g., 'Candles use batteries') and must decide as quickly as possible whether the sentence is true or false. Manous *et al.* combined this task with a sentence transcription task, in which listeners also wrote down each sentence after they verified it. The authors found that reaction times in the sentence verification task were related to the intelligibility of the type of speech in which the sentences were produced, as determined by the number of errors the listeners made in the sentence transcription task. Thus, the difficulty of encoding synthetic speech at the acoustic–phonetic level had a negative effect on the time course of the comprehension processes.

Figure 4 Response latencies for verification of false and true sentences, by voice type and length of sentence. Adapted with permission from Pisoni D B, Manous L M & Dedina M J (1987). 'Comprehension of natural and synthetic speech: effects of predictability on the verification of sentences controlled for intelligibility.' *Computer Speech and Language 2*, 303–320.

Pisoni *et al.* (1987) followed up on Manous *et al.*'s (1985) earlier findings by investigating whether the increased latencies for synthetic speech in the sentence verification task might also result from independent difficulties incurred in processing synthetic speech beyond the level of acoustic–phonetic surface structure. The authors replicated the methodology of Manous *et al.* using a DECTalk voice that did not induce significantly more errors than a natural voice in a sentence transcription task. Figure 4 shows the average response latencies from this study for both true and false sentences, broken down by the type of voice used and the length of the sentence (three or six words). The response latencies for true sentences were significantly higher for the DECTalk voice than they were for the natural voice, despite the close match between the two voices in segmental intelligibility. This finding indicated that DECTalk induced detrimental effects on the comprehension process that had no analogues at the level of segmental encoding. Pisoni *et al.*'s findings thus suggested that even the higher-level structures produced during the comprehension of synthetic speech were more impoverished – or more difficult to interpret – than the same structures produced during the comprehension of natural speech.

Message Complexity and Postperceptual Measures of Comprehension

Some postperceptual measures of comprehension have revealed differences in comprehension between synthetic and natural speech that appear to depend on the complexity of the information being processed. Moody and Joost (1986) asked listeners to answer multiple-choice questions from college and graduate entrance exams about passages that had been presented to them in both synthetic and natural voices. Hearing these passages in natural speech enabled the listeners to answer more of the questions correctly than hearing them in synthetic speech – but only if the questions dealt with the less complicated propositions in the passage. When the questions dealt with the more complex propositions, the number of correct answers the listeners gave was statistically the same, regardless of the type of voice the listeners had heard. Moody and Joost interpreted this result as evidence that listeners had to expend greater amounts

Figure 5 Average sentence-by-sentence listening times, by voice type and text difficulty. Adapted with permission from Ralston J V, Pisoni D B, Lively S E, Greene B G & Mullennix J W (1991). 'Comprehension of synthetic speech produced by rule: word monitoring and sentence-by-sentence listening times.' *Human Factors 33*, 471–491.

of cognitive effort in attempting to understand the more complex propositions in the passage. Similar to Luce (1981), Moody and Joost claimed that the application of these extra cognitive resources gave the listeners more robust representations of these propositions, which made them as easy to recall later as their natural counterparts.

Message Complexity and On-Line Measures of Comprehension

On-line measures have provided a different perspective on the relationship between message complexity and the comprehension of synthetic speech. Ralston *et al.* (1991) asked listeners to monitor for a small set of target words in a short passage presented in both natural and synthetic (Votrax) speech. Afterwards, the listeners answered a series of comprehension questions about different propositions in the passage they had just heard. Ralston *et al.* found that word-monitoring latencies were higher for synthetic words than for natural words, but only when those words appeared in propositions that were more difficult for the listeners to comprehend. Thus, the extra cognitive effort required to comprehend complicated propositions appears to detract from the lower-level process of word recognition, suggesting that both comprehension and word recognition may draw on the same, limited pool of cognitive processing resources.

Ralston *et al.* (1991) also reported results from a novel sentence-by-sentence listening task. In this task, participants listened to a series of sentences and pressed a button once they had understood one sentence and were ready to move on to the next. After listening to all the sentences, the listeners were tested on their memory of particular words or propositions in the sentences they had heard. Figure 5 shows the average amount of time it took listeners to move from one sentence to the next for both fourth-grade- and college-level passages presented in synthetic and natural speech. Listeners in this experiment took significantly longer to complete this task when the sentences were produced synthetically than when they were produced by a human voice. Ralston *et al.* found that sentence-by-sentence listening times were also highly correlated with the segmental intelligibility of each type of speech, suggesting that the time course of comprehension depends in large part on the amount of difficulty incurred in processing speech at the segmental level. However, the level of intelligibility did not account completely for the deficits in processing time, suggesting that independent difficulties in processing synthetic speech persisted beyond the level of acoustic–phonetic interpretation.

Paris *et al.* (1995) followed up on Ralston *et al.*'s (1991) work by asking listeners to shadow (i.e., immediately repeat what they heard) two passages of synthetic (DECTalk) or natural speech. After listening to these passages, the listeners answered a series of true/false questions about words and propositions that appeared in the various passages. Paris *et al.* found that shadowing accuracy was worse for DECTalk than it was for natural speech, even though there were no significant differences in either word or proposition recall between DECTalk and natural speech. The shadowing task thus provided another on-line measure of perceptual processing that revealed perceptual difficulties during the processing of even high-quality synthetic

speech that did not ultimately affect the final product of the speech comprehension process.

Finding 5: Perception of Synthetic Speech Improves with Experience

Improvement on Word and Sentence Recognition

Despite the fact that listeners consistently have more difficulty perceiving and comprehending synthetic speech than natural speech, their ability to perceive synthetic speech typically improves if they simply receive more exposure to it. Nye and Gaitenby (1973) found that listener performance on the MRT improved significantly over the course of their experiment, which included 150 different test words in each of six consecutive testing sessions. In the first of these sessions, listeners incorrectly identified 17.5% of the test words; in the last of these sessions, however, they misidentified only 8% of these words. Comparatively, listener performance on natural speech tokens in the MRT maintained an average error rate of approximately 4 or 5% throughout the six different testing sessions.

Carlson *et al.* (1976) also found that blind listeners' ability to repeat sentences of synthetic speech improved dramatically between the first and the last testing sessions in their experiment. Carlson *et al.*'s listeners heard a unique list of 25 sentences in each of eight separate testing sessions, the final four of which took place 1 week after the first four. The listeners correctly repeated 35% of the sentences in the first session but improved to 77% sentences correct in the final session. The listeners also maintained their improved performance over the weeklong break between the fourth and fifth sessions. The listeners thus demonstrated not only that significant improvements in the perception of synthetic speech can be made with relatively little exposure to it, but also that such improvements can be retained over longer term intervals.

An even more dramatic demonstration of the speed at which exposure to synthetic speech improves listeners' perceptual abilities was reported in Rounsefell *et al.* (1993). In this study, high school students received training on a particular synthetic voice by hearing only three repetitions of three different sentences produced by that voice. Each of these repetitions was followed by a live repetition of the same sentence, in a natural voice, by the experimenter. After this brief training session, the listeners were asked to transcribe a pair of sentences as produced by both a natural voice and the synthetic voice they had been trained on. Listeners who had received training were significantly better than untrained listeners at this sentence transcription task, even though they had only heard nine tokens of speech from the synthetic voice prior to testing.

Limits on the Extent of Perceptual Improvement

Although listeners' perception of synthetic speech may improve rapidly after a few initial exposures, such improvement does not continue indefinitely. Venkatagiri (1994) had listeners perform a sentence transcription task over 3 consecutive days and found that significant increases in improvement tapered off after the second day of testing. However, Venkatagiri noted that a lack of significant perceptual improvement after the second day of testing may have been due to a ceiling effect since the average percentage of correct transcriptions had already improved from 78.2 to 94.1% between days 1 and 2 but could only increase to 96% on day 3. A task that listeners could not perform as well as the sentence transcription task might therefore yield continued perceptual improvements from exposure to synthetic speech over a longer period of time.

Slowiaczek and Pisoni (1982) found that listeners displayed continued improvement in the perception of synthetic speech when tested on an auditory lexical decision task over 5 consecutive days. Figure 6 shows the average response times and the percentages of errors listeners made in this task while listening to both synthetic and natural stimuli for the second through the fifth days of testing. This figure reveals two trends in the listeners' responses to the nonword stimuli: Response times for natural and synthetic items continued to decrease significantly over the 5 days of testing; however, the corresponding proportions of correct responses remained essentially constant for the duration of the study. This pattern suggests that response time measurements might reflect continued improvements in perception even though performance as defined by a coarser-grained behavioral measure, such as response accuracy, may have already reached ceiling.

Improvement in Comprehension

Despite the continued improvement that listeners may display in processing synthetic stimuli in the lexical decision task, it has been shown that the comprehension of synthetic speech can probably never improve to the same level as the comprehension of natural speech. Reynolds *et al.* (2002) demonstrated this by testing listeners on a sentence verification task, using both natural and DECTalk-produced sentence stimuli, over 5 consecutive days. On all 5 days, sentence verification reaction times (RTs) were shorter

Figure 6 Lexical decision response times and errors for words and nonwords, by voice type and day of study. Adapted with permision from Slowiaczek L M & Pisoni D B (1981). 'Effects of practice on speeded classification of natural and synthetic speech.' In *Research on speech perception progress report No. 7.* Bloomington, IN: Speech Research Laboratory, Indiana University. 255–262.

for natural sentences than they were for synthetic sentences. RTs also decreased significantly for both types of sentences between the first and the last day of the experiment. However, the future course of RT improvement for both types of sentences – as determined by using a regression analysis – indicated that RTs to natural and synthetic sentences would diverge past the fifth day of testing. Although listener performance would continue to improve for both voices, the continued listener improvement on the natural voice would be greater than the continued improvement on the synthetic voice. Hence, no matter how much listeners were exposed to synthetic speech, their ability to comprehend it would still remain worse than their ability to comprehend natural speech, given equivalent amounts of practice listening to both types of voices in the sentence verification testing paradigm.

Perceptual Learning vs. Practice Effects

Schwab *et al.* (1985) found that improvement in the perception of synthetic speech depends on actual exposure to synthetic speech and is not just the result of practice on a particular perceptual task. Schwab *et al.* tested listeners on a variety of perceptual tasks using synthetic (Votrax) speech stimuli and then trained them on the same tasks using either natural or synthetic (Votrax) stimuli. After 8 days of training, they retested all listeners on the same tasks using Votrax stimuli. Schwab *et al.* found that the listeners who had been trained with synthetic stimuli had significantly improved their performance between pre- and posttest. The listeners who had been trained on the tasks while listening to natural stimuli, however, did not improve more than a control group that had received no training on the tasks. Schwab *et al.* thus argued that perceptual improvement

depended on exposure to synthetic speech *per se*, suggesting that listeners became better at extracting acoustic–phonetic information from the synthetic speech signal as they gained increasing amounts of exposure to it. This ability is evidently stimulus specific and cannot be gained by simply being exposed to equivalent amounts of natural speech. Interestingly, Schwab *et al*. ran a follow-up study 6 months after the original training experiment that showed that the group that had been trained with synthetic speech still maintained better levels of performance on a range of perceptual tasks using synthetic stimuli than the group that had been trained with natural speech. The effects of perceptual learning thus have long-term benefits for the perception of synthetic speech.

Improvement on the perception of synthetic speech in a particular behavioral task may also occur without practice on that task, as long as listeners receive exposure to synthetic speech in some form. Reynolds *et al*. (2000) demonstrated that listeners' comprehension of synthetic speech – as measured by their performance on a sentence verification task – can improve in this way. Between a sentence verification pretest and posttest, Reynolds *et al*. trained one group of listeners for 8 consecutive days on a sentence transcription task, in which they heard the same synthetic voice (DECTalk) that they had heard in the pretest. Another group of listeners received no training or exposure to synthetic speech between the pre- and the posttest. The trained listeners showed more improvement on the sentence verification task between pre- and posttest than did the untrained listeners, even though they had not explicitly practiced this task during training.

Generalization of Perceptual Learning

Greenspan *et al*. (1988) adapted the training paradigm developed by Schwab *et al*. to determine whether there were limits on the ability of listeners to generalize their improved perception of a particular set of synthetic speech stimuli in training to novel synthetic speech stimuli in testing. Greenspan *et al*. found that such limitations do exist, in that listeners cannot generalize from training on individual words to improve their perception of whole sentences. In their study, Greenspan *et al*. initially tested listeners on a variety of word and sentence recognition tasks. They then trained one group of listeners on word recognition tasks and another group of listeners on sentence transcription tasks. After 4 days, all listeners underwent the same battery of tests as they had on the first day of the experiment. Greenspan *et al*. found that the listeners who had received training on sentence transcription showed improved performance on both word and sentence recognition on the final day of testing. The listeners who had received training on word recognition, however, only showed improved performance on the word recognition tasks; their performance on the sentence recognition tasks had not improved at all. The failure of the listeners to generalize from individual word training to sentence transcription probably resulted from their inability to parse the word boundaries in a stream of synthetic speech. The ability of listeners to generalize their improvement in sentence transcription to the word recognition task, on the other hand, most likely resulted from the listeners being exposed to a large number of synthetic words in a wide range of contexts during the 4 days of training.

Greenspan *et al*. (1988) also tested the hypothesis that variability in training stimuli crucially determines whether listeners can generalize perceptual improvement in training to novel stimuli in testing. In this study, Greenspan *et al*. trained two different listener groups on the phonetically balanced (PB) word recognition task. After a pretest, one group of listeners received training on this task with novel words, whereas another group received training on only repetitions of words they had already heard in the pretest. In a posttest, both groups of listeners showed improvement in their ability to perceive novel words; however, the group that had heard novel training stimuli showed more improvement than the group that had heard repeated stimuli. Improvement in the perception of synthetic speech thus appears to depend, to a large extent, on the amount of acoustic–phonetic variability in the synthetic speech samples that listeners are exposed to during training.

Finding 6: Alternative Populations of Listeners Process Synthetic Speech Differently

The studies reviewed previously all found consistent perceptual deficits in the processing of synthetic speech by listeners who were college-aged, normal-hearing, native speakers of English. Other studies have found, however, that alternative populations of listeners can have even more difficulty processing synthetic speech than their young, normal-hearing counterparts.

Nonnative Listeners

Greene (1986) found that nonnative listeners of English have significantly more difficulty perceiving synthetic speech (in English) than do native listeners.

Nonnative listeners performed worse than native listeners on the MRT when they heard both natural and synthetic stimuli; however, the performance gap between the two groups increased significantly when they heard the synthetic items. Native listeners were also better than nonnative listeners at transcribing natural and synthetic sentences, but this perceptual advantage did not interact with the type of voice the listeners heard. The nonnative listeners' ability to transcribe synthetic sentences was highly variable but appeared to depend strongly on their proficiency in the English language. Reynolds *et al.* (1996) also confirmed that nonnative listeners have more difficulty perceiving synthetic speech in noise than do native listeners.

Children

Greene and Pisoni (1988) showed that school-aged children have considerable difficulty processing synthetic speech. Both kindergartners and second-graders had less success identifying synthetic words in a picture matching task than they had identifying natural words. The second-graders performed significantly better on this task than the kindergartners, however, indicating that children's ability to perceive synthetic speech improves rapidly as they mature. Greene (1983) also found that fourth-graders were less successful at recalling synthetic words than they were at recalling natural words.

Mirenda and Beukelman (1987) directly compared the performance of adults and children on word and sentence repetition tasks using natural and synthetic stimuli. Children in this study consistently performed worse than adults in repeating both natural and synthetic words, and younger listeners – from 6 to 8 years old – also performed worse than children between the ages of 10 and 12 years in repeating synthetic words. The children's performance improved in the sentence repetition task, suggesting that they, like adults, were able to draw on higher-level linguistic knowledge to interpret whole synthetic sentences. However, since the adults' repetition scores improved more in the sentence transcription task than did the children's scores, adult listeners appeared to be better at accessing and using this higher-level linguistic knowledge than the children.

Using a sentence verification task, Reynolds and Fucci (1998) showed that children also have more difficulty comprehending synthetic speech than natural speech. Reynolds and Jefferson (1999) expanded on this finding by testing child listeners from two separate age groups – 6 or 7 years old and 9–11 years old – in an identical experimental paradigm. They found an equivalent processing advantage for natural versus synthetic sentences for all listeners but also found that the 9- to 11-year-olds verified both kinds of sentences faster than the 6- or 7-year-olds. This pattern of results mirrored the findings of Mirenda and Beukelman (1987, 1990) for similar groups of listeners performing repetition tasks. Thus, the differences in sentence verification times between 6- or 7-year-old and 9- to 11-year-old listeners may be due to the corresponding difficulties each group has in interpreting and encoding the acoustic–phonetic structure of synthetic speech rather than independent difficulties at higher levels of linguistic processing.

Hearing-Impaired and Older Listeners

Most studies investigating older listeners' perception of synthetic speech have been carried out within the context of studying hearing impairment and its potential effects on the perception of synthetic speech. Kangas and Allen (1990), for instance, tested two groups of listeners between the ages of 49 to 64 years in a word recognition task; one group had normal hearing, whereas the other was hearing-impaired. Hearing-impaired listeners performed worse on this task than did normal-hearing listeners. However, there was no interaction between voice type and listener group, suggesting that the poor performance of the hearing-impaired listeners could be accounted for by combining the deficits that synthetic speech and hearing impairment impose independently on normal speech perception processes.

Humes *et al.* (1991) established that age also does not interact with hearing-impaired listeners' perception of synthetic speech. They tested a group of 66- to 73-year-old hearing-impaired listeners and two groups of 19- to 22-year-old listeners on the MRT. One group of 19- to 22-year-old listeners heard the MRT items in the clear, whereas the other heard them through spectrally shaped noise, which was designed to mimic the effects of hearing loss in the 66- to 73-year-olds. Figure 7 shows the percentage of word recognition errors each group of listeners made while listening to the MRT items as produced by natural, DECTalk, and Votrax voices. Although the younger listeners who heard the stimuli in the clear were better at the MRT than either of the other groups of listeners, no significant differences in performance were observed between the hearing-impaired listeners and the young listeners who heard the stimuli through spectrally shaped noise. The decreased level of performance on the MRT by the older, hearing-impaired listeners could therefore

Figure 7 Percentage of words correctly identified on the MRT, by voice type and listener group. NH, normal-hearing; HI, hearing-impaired; MN, masked-noise. Adapted with permission from Humes L E, Nelson K J, Pisoni D B & Lively S E (1993). 'Effects of age on serial recall of natural and synthetic speech.' *Journal of Speech and Hearing Research 34*, 1180–1184.

be accounted for solely by their hearing impairment, independently of their age.

In another study, Humes *et al.* (1993) showed that older listeners (61–76 years old) have more difficulty recalling synthetic words than younger listeners (21–24 years old). However, they failed to find significant differences in performance between older and younger listeners on a sentence transcription task, indicating that the processing of synthetic speech at the segmental level did not significantly deteriorate with age in normal-hearing listeners.

Expert Listeners

Extensive experience listening to synthetic speech can enable listeners to become 'experts' at extracting acoustic–phonetic information from synthetic speech signals. Hustad *et al.* (1998) demonstrated that listeners who had worked with synthetic speech for at least 5 h a day for more than 1 year, identified synthetic words in the MRT significantly better than either speech pathologists or listeners who were unfamiliar with synthetic speech. Hustad *et al.* also found that similar amounts of experience listening to natural speech in an analytic fashion by the speech language pathologists had not improved their perception of synthetic speech beyond the level of the inexperienced listeners.

Finding 7: Prosody and Naturalness Interact with the Acceptability and Intelligibility of Synthetic Speech

Subjective Evaluations and Naturalness

Research on the perception of synthetic speech's prosodic characteristics and naturalness has primarily relied on subjective evaluations of synthetic speech rather than direct behavioral measures of performance in listening tasks. Nusbaum *et al.* (1984) found that listeners tend to prefer natural speech to synthetic speech by simply asking listeners to rate synthetic and natural voices on a variety of impressionistic scales (e.g., interesting vs. boring). They also found that listeners' confidence in their comprehension of synthetic passages was much lower than their confidence in their comprehension of natural passages, even though their performance in a comprehension task did not differ between natural and synthetic voices. This result suggested that subjective evaluations might capture more subtle difficulties in the process of comprehending synthetic speech that could elude postperceptual measures of comprehension.

Terken and Lemeer (1988) found that subjective evaluations of the 'attractiveness' of synthetic speech depend on both its segmental intelligibility and its prosodic characteristics. Listeners judged highly intelligible sentences with natural prosody to be more attractive than those produced in monotone; however, listeners rated low-intelligibility sentences as equally unattractive, regardless of their prosodic characteristics. Terken and Lemeer concluded that the perception of prosody in synthetic speech depends on a high level of segmental intelligibility.

Nusbaum *et al.* (1995) attempted to develop a behavioral measure of 'naturalness' that was independent of intelligibility. They low-pass filtered synthetic and natural speech samples and then asked listeners to identify whether the stimuli had been produced by a 'human' or a 'computer.' Low-pass filtering renders speech unintelligible by removing segmental cues, but it does preserve the prosodic characteristics of the source signal. Using this prosodic information alone, Nusbaum *et al.* found that listeners reliably identified a human voice as human more often than either DECTalk or Votrax speech, and they identified DECTalk speech as human more often than Votrax speech. By equating the naturalness of a voice with the percentage of times it was identified as human in this task, Nusbaum *et al.* concluded that listener identification of the voice source of low-pass filtered speech could provide a reliable, intelligibility-free measure of the perceived naturalness of a voice.

Evaluating Prosodic Quality

Some researchers have used subjective assessments to evaluate the quality of particular prosodic features in synthetic speech. Terken (1993), for instance, found that synthetic speech that included phrase boundaries sounded more natural to experienced phoneticians than synthetic speech without phrase boundaries. Terken also found that scrambling the order of sentences in a naturally produced passage eliminated its perceived naturalness advantage over a comparable synthetic passage. This result indicated that there are discourse-level prosodic structures in passages of natural speech that help them sound natural.

Sanderman and Collier (1996) also investigated the subjective acceptability of implementing certain prosodic rules in synthetic speech. They expanded Terken's (1993) prosodic rule sets and found not only that appropriate prosody becomes a more important contributor to the naturalness of synthetic speech the longer the synthetic speech segment becomes, but also that greater amounts of variability in the implementation of prosodic rules significantly improve the perceived naturalness of synthetic speech.

Appropriate Prosody Improves Comprehension and Intelligibility

Some research has shown that prosody may not only improve the perceived naturalness of synthetic speech but also facilitate its comprehension and intelligibility. For instance, Slowiaczek and Nusbaum (1985) found that incorporating a 'hat pattern' pitch contour into declarative sentences that were produced synthetically improved listener transcription of those sentences – but only if the syntactic structure of each sentence was not predictable. Otherwise, listeners transcribed the sentences equally well when they had a monotone pitch contour.

Sanderman and Collier (1997) also showed that appropriate prosody can facilitate the comprehension of syntactically ambiguous sentences, such as 'I reserved a room in the hotel with the fax.' Listeners are inherently biased toward one interpretation of these sentences over another. When Sanderman and Collier played these sentences to listeners with a prosodic pattern that supported the preferred interpretation, the time it took for listeners to comprehend the sentences decreased in comparison to a neutral prosody condition. When the listeners heard the sentences with a prosodic pattern that conflicted with the preferred interpretation, however, comprehension time increased over the neutral prosody condition. Thus, appropriate prosodic phrasing for synthetic sentences seems to be necessary for the optimal comprehension of synthetic speech, but inappropriate prosodic phrasing may actually make it more difficult, under certain conditions, for listeners to comprehend synthetic speech.

Despite the potential benefits of appropriate prosody to the perception of synthetic speech, Paris *et al.* (2000) found that the sentence-level prosodic cues in even high-quality synthetic speech (DECTalk) did not improve the recall of synthetically produced sentences. However, natural sentence-level prosody did facilitate the recall of naturally produced sentences as well as significantly improve their perceived naturalness and intelligibility. Improving the quality of sentence- and passage-level prosodic structures in synthetic speech thus remains an important step to take toward optimizing its naturalness, intelligibility, and acceptability.

Conclusions and Directions for Future Research

Applicability of Synthetic Speech

Many of the research findings on the perception of synthetic speech have important implications for the practical application of speech synthesis. For instance, the fact that the segmental intelligibility of synthetic speech deteriorates significantly in noisy listening conditions suggests that synthetic speech applications likely have limited utility in noisy work environments, outdoors, or over cell phones. Investigating ways to overcome these limitations on synthetic speech intelligibility, however, can provide some promising avenues for future research. For instance, audiovisual speech synthesis (Cohen and Massaro, 1994; Ezzat and Poggio, 2000) may improve the intelligibility of synthetic speech in noise since visible speech cues have been shown to substantially boost the intelligibility of natural speech stimuli in noise (Sumby and Pollack, 1954). Although viable systems for producing synthetic visual speech do exist, it is not known how the visual-only perception of synthetic speech may differ from the visual-only perception of natural speech. It is also unknown whether synthetic visual speech can improve the intelligibility of synthetic speech in noise as much as natural visual cues improve the intelligibility of natural speech in noise. Answering basic research questions such as these may prove important not only to our future understanding of the utility of audiovisual speech synthesis, but also to our understanding of the visual aspects of natural speech that are important to multimodal perception (Calvert *et al.*, 2004).

The perception of synthetic speech also requires more cognitive processing resources than the perception of natural speech. One increasingly popular

application of speech synthesis is to provide spoken driving directions from computerized navigation systems in automobiles. The drivers who need to understand these spoken directions must do so under a significant cognitive load in frequently noisy listening conditions. Determining how to improve the intelligibility of synthetic speech under these demanding listening conditions should therefore improve the viability and safety of such synthetic speech applications.

The potential for success of any synthetic speech application also depends on the particular listener who is using it. Children, nonnative speakers, listeners with hearing impairments, and the elderly all have more difficulty understanding synthetic speech than young, normal-hearing, college-aged listeners. However, the ability of all listeners to extract information from synthetic speech tends to improve the more they are exposed to it. Extensive exposure to a particular form of synthetic speech, in fact, may enable 'expert listeners' to develop abilities to perceive synthetic speech that far surpass those of listeners who are normally studied in synthetic speech perception experiments. Research on such expert listeners may reveal what upper limits (if any) exist on the human ability to extract information from synthetic speech and may also determine if extensive amounts of listening experience can close the gap in intelligibility between synthetic and natural speech.

Theoretical Implications

The poor intelligibility of synthetic speech produced by rule indicates that those aspects of natural speech that rule-based algorithms fail to capture (e.g., variability, acoustic–phonetic cue redundancy, and sentence-level prosody) play important roles in making natural speech highly intelligible and perceptually robust. 'Concatenative' speech synthesis, however, uses natural human utterances as a voice source and thus incorporates, to some extent, the rich variability and cue redundancy inherent in natural speech. The existing research on the intelligibility of concatenative versus rule-based synthesis (Venkatagiri, 2003) indicates that concatenative synthesis produces highly intelligible consonants, for which it preserves the natural cues and formant transitions, but somewhat less intelligible vocalic segments, in which the discontinuities between concatenated source units typically exist.

The findings reviewed here confirm that the acoustic–phonetic redundancy and variability inherent in natural speech are, indeed, important to perception. However, future research needs to investigate further the differences that may exist in perception between concatenative and formant synthesis, as well as the specific role that acoustic–phonetic variability plays in speech perception. There are many sources of variability in speech (e.g., speaker, dialect, gender, age, emotional state, and social identity) and little is known about how these sources of variability facilitate speech perception and spoken word recognition. Incorporating different sources of variability into synthetic speech provides a straightforward way of testing their effects on speech intelligibility and may, in turn, ultimately provide a valuable means of improving the overall intelligibility of synthetic speech (Stevens, 1996).

Improving the quality of synthetic speech also requires a much better understanding of what makes synthetic speech sound 'unnatural' to most human listeners. Generating appropriate prosodic contours appears to improve the perceived naturalness of synthetic speech, and this in turn appears to increase its perceived intelligibility (Paris *et al.*, 2000). Determining the appropriateness of particular prosodic contours, however, has proven difficult because listeners cannot, in general, describe the prosodic information they perceive in linguistic terms. Thus, future research may have to develop new assessment methods to investigate the indirect effects that prosodic structure has on the processing of synthetic speech (Pisoni, 1997a).

Developing new experimental methods that can target higher-level comprehension processes may also enable researchers to investigate and identify the scope of the detrimental effects of synthetic speech on the human language comprehension system. Duffy and Pisoni (1992) observed that the phonological encoding of speech stimuli must begin before listeners start to interpret message-level information, even though processing at both levels may continue later simultaneously. Synthetic speech makes language processing more difficult at both the phonological and message levels; however, it is unclear whether this is due solely to the difficulty of interpreting synthetic speech at the phonological level, which may have cascading effects on subsequent stages in the comprehension process, or also because of independent processing difficulties incurred by synthetic speech at the stage of message-level semantic interpretation. Developing new behavioral measures that assess higher-level comprehension processes, independently of low-level phonemic encoding effects, could help clarify whether synthetic speech causes perceptual deficits at the level of segmental interpretation alone or whether it also causes independent problems for semantic processing. Examining how these distinct levels of processing interact with one

another in the perception of synthetic speech may shed light on how these levels operate together in the comprehension of natural speech as well.

Considerations such as these on the future direction of research on the perception of synthetic speech reflect the fact that speech scientists will likely have to develop new and more sophisticated behavioral assessment methods to keep pace with the rapid progress of speech synthesis technology. Only in this way can research on the perception of synthetic speech continue to have direct, practical benefits for speech synthesis technology as well as provide a unique opportunity for speech scientists to investigate those features of speech that make the perception of natural speech so robust and the perception of synthetic speech so difficult.

Speech Synthesis: Prosody

J Hirschberg, Columbia University, New York, NY, USA

© 2006 Elsevier Ltd. All rights reserved.

Text-to-speech (TTS) systems take unrestricted text as input and produce a synthetic spoken version of that text as output. During this process, the text input must be analyzed to determine the prosodic features that will be associated with the words that are produced. For example, if a sentence of English ends in a question mark and does not begin with a WH-word, that sentence may be identified as a yes–no question and produced with a rising 'question' contour. If the same word occurs several times in a paragraph, the system may decide to realize that word with less prosodic prominence on these subsequent mentions.

These decisions are known as 'prosodic assignment decisions.' Once they have been made, they are passed along to the prosody modeling component of the system to be realized in the spoken utterance by specifying the appropriate pitch contour, amplitude, segment durations, and so on. Prosodic variation will differ according to the language being synthesized and also according to the degree to which the system attempts to emulate human performance and succeeds in this attempt.

Issues for Prosodic Assignment in TTS

No existing TTS system, for any language, controls prosodic assignment or its realization entirely successfully. For most English synthesizers, long sentences that lack commas are uttered without 'taking a breath' so that it is almost impossible to remember the beginning of the sentence by the end; synthesizers that do attempt more sophisticated approaches to prosodic phrasing often make mistakes (e.g., systems that break sentences between conjuncts overgeneralize to phrasing such as 'the nuts | and bolts approach'). Current approaches to assigning prosodic prominence in TTS systems for pitch accent languages, such as English, typically fail to make words prominent or nonprominent as human speakers do. Since many semantic and pragmatic factors may contribute to human accenting decisions and these are not well understood, and since TTS systems must infer the semantic and pragmatic aspects of their input from text alone, attempts to model human performance in prominence decision have been less successful than modeling phrasing decisions. For most systems, the basic pitch contour of a sentence is varied only by reference to its final punctuation; sentences ending with '.', for example, are always produced with the same standard 'declarative' contour, contributing to a numbing sense of monotony. Beyond these sentence-level prosodic decisions, few TTS systems attempt to vary such other features as pitch range, speaking rate, amplitude, and voice quality in order to convey the variation in intonational meaning that humans are capable of producing and understanding.

Many TTS systems have addressed these issues using more or less sophisticated algorithms to vary prominence based on a word's information status or to introduce additional phrase boundaries based on simple syntactic or positional information. Although some of these algorithms have been constructed 'by hand,' most have been trained on fairly large speech corpora, hand-labeled for prosodic features. However, since prosodic labeling is very labor-intensive, and since the variety of prosodic behavior that humans vary in normal communication is very large and the relationship between such behaviors and automatically detectable features of a text is not well understood, success in automatic prosodic assignment in TTS systems has not improved markedly in recent years. Failures of prosodic assignment represent the largest source of 'naturalness' deficiencies in TTS systems today.

Prosody in TTS Systems

Prosodic variation in human speech can be described in terms of the pitch contours people employ, the items within those contours that people make intonationally prominent, and the location and importance of prosodic phrase boundaries that bound contours. In addition, human speakers vary pitch range, intensity or loudness, and timing (speaking rate and the location and duration of pauses) *inter alia* to convey differences in meaning. TTS systems ideally should vary all these dimensions just as humans do.

To determine a model of prosody for a TTS system in any given language, one must first determine the prosodic inventory of the language to be modeled and which aspects of that inventory can be varied by speakers to convey differences in meaning: What are the meaningful prosodic contrasts in this language? How are they realized? Do they appear to be related (predictable) in some way from an input text? How does the realization of prosodic features in the language vary based on the segments being concatenated? What should the default pitch contour be for this language (usually, the contour most often used with 'declarative' utterances)? What contours are used over questions? What aspects of intonation can be meaningfully varied by speakers to contribute to the overall meaning of the utterance? For example, in tonal languages such as Mandarin, how do tones affect the overall pitch contour (e.g., is there 'tone sandhi,' or influence on the realization of one tone from a previous tone?)? Also, in languages such as Japanese, in which pitch accent is lexically specified, what sort of free prominence variation is nonetheless available to speakers? These systems must also deal with the issue of how to handle individual variation – in concatenative systems, whether to explicitly model the speaker recorded for the system or whether to derive prosodic models from other speakers' data or from abstract theoretical models. Although modeling the recorded speaker in such systems may seem the more reasonable strategy, so as to avoid the need to modify databases more than necessary in order to produce natural-sounding speech, there may not be enough speech recorded in the appropriate contexts for this speaker to support this approach, or the prosodic behavior of the speaker

may not be what is desired for the TTS system. In general, though, the greater the disparity between a speaker's own prosodic behavior and the behavior modeled in the TTS system, the more difficult it is to produce natural-sounding utterances.

Whatever their prosodic inventory, different TTS systems, even those that target the same human language, will attempt to produce different types of prosodic variation, and different systems may describe the same prosodic phenomenon in different terms. This lack of uniformity often makes it difficult to compare TTS systems' capabilities. It also makes it difficult to agree on common TTS markup language conventions that can support prosodic control in speech applications, independent of the particular speech technology being employed.

TTS systems for most languages vary prosodic phrasing, although phrasing regularities of course differ by language; phrase boundaries are produced at least at the end of sentences and, for some systems, more elaborate procedures are developed for predicting sentence-internal breaks as well. Most systems developed for pitch accent languages such as English also vary prosodic prominence so that, for example, function words such as 'the' are produced with less prominence than content words such as 'cat.' The most popular models for describing and modeling these types of variation include the Edinburgh Festival Tilt system and the ToBI system, developed for different varieties of English prosody, the IPO contour stylization techniques developed for Dutch, and the Fujisaki model developed for Japanese. These models have each been adapted for languages other than their original target: thus, there are Fujisaki models of English and ToBI models of Japanese, *inter alia*. The following section specifies prosodic phenomena in the ToBI model for illustrative purposes. The ToBi model was originally developed for standard American English; a full description of the conventions as well as training materials may be found at http://ling.ohio-state.edu/~tobi.

The ToBI System

The ToBI system consists of annotations at four time-linked levels of analysis: an 'orthographic tier' of time-aligned words; a 'break index tier' indicating degrees of junction between words, from 0 (no word boundary) to 4 (full intonational phrase boundary); and a 'tonal tier,' where pitch accents, phrase accents, and boundary tones describing targets in the fundamental frequency (f0) define prosodic phrases, following Pierrehumbert's scheme for describing American English, with modifications; and a miscellaneous tier, where additional phenomena such as disfluencies may be marked. Break indices define two levels of phrasing, minor or intermediate (level 3) and major or intonational (level 4), with an associated tonal tier that describes the phrase accents and boundary tones for each level. Level 4 phrases consist of one or more level 3 phrases plus a high or low boundary tone (H% or L%) at the right edge of the phrase. Level 3 phrases consist of one or more pitch accents, aligned with the stressed syllable of lexical items, plus a phrase accent, which also may be high (H-) or low (L-). A standard declarative contour for American English, for example, ends in a low phrase accent and low boundary tone and is represented by H* L-L%; a standard yes–no question contour ends in H-H% and is represented as L* H-H%. Five types of pitch accent occur in the ToBI system defined for American English: two simple accents (H* and L*) and three complex ones (L*+H, L+H*, and H+H*). As in Pierrehumbert's system, the asterisk indicates which tone is aligned with the stressed syllable of the word bearing a complex accent. Words associated with pitch accents appear intonationally prominent to listeners and may be termed 'accented'; other words may be said to be 'deaccented.' This scheme has been used to model prosodic variation in the Bell Labs and AT&T TTS systems and also as one of several models in the Festival TTS system.

Prosodic Prominence

In many languages, human speakers tend to make content words (nouns, verbs, and modifiers) prosodic prominent or accented – typically by varying some combination of f0, intensity, and durational features – and function words (determiners and prepositions) less prominent or deaccented. Many early TTS systems relied on this simple content/function distinction as their sole prominence assignment strategy. Although this strategy may work fairly well for short, simple sentences produced in isolation, it works less well for longer sentences and for larger stretches of text.

In many languages, particularly for longer discourses, human speakers vary prosodic prominence to indicate variation in the information status of particular items in the discourse. In English, for example, human speakers tend to accent content words when they represent items that are 'new' to the discourse, but they tend to deaccent content words that are 'old,' or given, including lexical items with the same stem as previously mentioned words. However, not all given content words are deaccented, making the relationship between the given/new distinction and the accenting decision a complex one. Given items can be accented because they are used in a

contrastive sense, for reasons of focus, because they have not been mentioned recently, or other considerations.

For example, in the following text, some content words are accented but some are not:

> The **SENATE BREAKS** for **LUNCH** at **NOON**, so i **HEADED** to the **CAFETERIA** to **GET** my **STORY**. There are **SENATORS**, and there are **THIN** senators. For **SENATORS**, **LUNCH** at the cafeteria is **FREE**. For **REPORTERS**, it's not. But **CAFETERIA** food is **CAFETERIA** food.

TTS systems that attempt to model human accent decisions with respect to information status typically assume that content words that have been mentioned in the current paragraph (or some other limited stretch of text) and, possibly, words sharing a stem with such previously mentioned words should be deaccented, and that otherwise these words should be accented. However, corpus-based studies have shown that this strategy tends to deaccent many more words than human speakers would deaccent. Attempts have been made to incorporate additional information by inferring 'contrastive' environments and other factors influencing accent decisions in human speakers, such as complex nominal (sequences of nouns that may be analyzed as 'noun–noun' or as 'modifier–noun') stress patterns. Nominals such as *city **HALL*** and ***PARKING** lot* may be stressed on the left or the right side of the nominal. Although a given nominal is typically stressed either on the right or the left, determining which automatically is an unsolved problem, despite some identified semantic regularities, such as the observation that room descriptions (e.g., ***DINING** room*) typically have left stress and street names (e.g., ***MAIN** Street*), although not avenues or roads, do as well. More complicating in English complex nominals is the fact that combinations of complex nominals may undergo stress shift, such that adjoining prominent items may cause one of the stresses to be shifted to an earlier syllable (e.g., ***CITY** hall **PARKING** lot*).

Other prominence decisions are less predictable from simple text analysis since they involve cases in which sentences can, in speech, be disambiguated by varying prosodic prominence in English and other languages. Such phenomena include ambiguous verb–particle/preposition constructions (e.g., *George moved behind the screen*, in which accenting *behind* triggers the verb–particle interpretation), focus-sensitive operators (e.g., *John only introduced Mary to Sue*, in which the prominence of *Mary* vs. *Sue* can favor different interpretations of the sentence), differences in pronominal reference resolution (e.g., *John called Bill a Republican and then he insulted him*, in which prominence on the pronouns can favor different resolutions of them), and differentiating between discourse markers (words such as *well* or *now* that may explicitly signal the topic structure of a discourse) and their adverbial homographs (e.g., *Now Bill is a vegetarian*). These and other cases of ambiguity which can be disambiguated prosodically can only be modeled in TTS by allowing users explicit control over prosody. Disambiguating such sentences by text analysis is currently beyond the range of natural language processing systems.

Prosodic Phrasing

Prosodic phrasing decisions are important in most TTS systems. Human speakers typically 'chunk' their utterances into manageable units, producing phrase boundaries with some combination of pause, f0 change, a lessening of intensity, and often lengthening of the word preceding the phrase boundary. TTS systems that attempt to emulate natural human behavior try to produce phrase boundaries modeling such behavior in appropriate places in the input text, relying on some form of text analysis.

Intuitively, prosodic phrases divide an utterance into meaningful units of information. Variation in phrasing can change the meaning hearers assign to a sentence. For example, the interpretation of a sentence such as *Bill doesn't drink because he's unhappy* is likely to change, depending on whether it is uttered as one phrase or two. Uttered as a single phrase, with a prosodic boundary after *drink*, this sentence is commonly interpreted as conveying that Bill does indeed drink, but the cause of his drinking is not his unhappiness. Uttered as two phrases (*Bill doesn't drink – because he's unhappy*), it is more likely to convey that Bill does not drink – and that unhappiness is the reason for his abstinence. In effect, variation in phrasing in such cases in English, Spanish, and Italian, and possibly other languages, influences the scope of negation in the sentence. Prepositional phrase (PP) attachment has also been correlated with prosodic phrasing: *I saw the man on the hill – with a telescope* tends to favor the verb phrase attachment, whereas *I saw the man on the hill with a telescope* tends to favor an noun phrase attachment.

Although phrase boundaries often seem to occur frequently in syntactically predictable locations such as the edges of PPs, between conjuncts, or after preposed adverbials, *inter alia*, there is no necessary relationship between prosodic phrasing and syntactic structure – although this is often claimed by more theoretical research on prosodic phrasing. Analysis of prosodic phrasing in large prosodically labeled

corpora, particularly in corpora of nonlaboratory speech, shows that speakers may produce boundaries in any syntactic environment. Although some would term such behavior 'hesitation,' the assumption that phrase boundaries that occur where one does not believe they should must result from some performance difficulty is somewhat circular. In general, the data seem to support the conclusion that syntactic constituent information is one useful predictor of prosodic phrasing but that there is no one-to-one mapping between syntactic and prosodic phrasing.

Overall Contour Variation

TTS systems typically vary contour only when identifying a question in the language modeled, if that language does indeed have a characteristic 'question' contour. English TTS systems, for example, generally produce all input sentences with a falling 'declarative' contour, with only yes–no questions and occasionally sentence-internal phrases produced with some degree of rising contour. This limitation is a considerable one since most languages exhibit a much richer variety of overall contour variation. English, for example, employs contours such as the 'rise–fall–rise' contour to convey uncertainty or incredulity, the 'surprise-redundancy' contour to convey that something observable is nonetheless unexpected, the 'high-rise' question contour to elicit from a hearer whether some information is familiar to that hearer, and the 'plateau' contour ('You've already heard this') or 'continuation rise' ('There's more to come'; L-H% in ToBI) as variants of list intonation and 'down-stepped' contours to convey, *inter alia*, the beginning and ending of topics.

Systems that attempt to overcome the monotony of producing the same contour over most of the text they synthesize do so in the main by allowing users to specify contour variation (as well as phrasing, accent, and other prosodic features) by using some form of markup language within the input text. Recent interest in the production of different TTS voices and of different listener impressions of the state or emotion of the speech being produced has led to some renewed interest in the relationship between pitch contour and speaker personality and speaker state. This research is still in the early stages, but thus far it has not been demonstrated empirically that speaker state (except perhaps for 'boredom'), at least, can be signaled effectively by mere contour variation: voice quality, speaking rate, intensity, and pitch range also must be involved.

Varying Timing and Pitch Range

Two additional prosodic features that TTS systems may vary in attempting to mimic human behavior are timing and pitch range. Timing parameters may include speaking rate and pausal duration between prosodic phrases. Speakers may vary their rate to convey a different interpretation of a particular pitch contour, convey some emotional state, indicate that a phrase should be interpreted as a parenthetical remark, or convey differences in topic structure. Pitch range can also produce different 'meanings' for a given pitch contour or convey differences in discourse/topic structure. It can also indicate differences in a speaker's degree of involvement. In TTS systems, pitch range variation generally involves controlling the expansion and contraction of the overall f0 range for an utterance, parameters that may be calculated in different ways depending on the prosodic model being implemented in the system. For example, if paragraphing is used as a proxy for topic structure, systems will expand their pitch range over the first phrase of the paragraph and conclude with a phrase in a more compressed range.

Predicting Prosodic Features from Text

Once a prosodic model has been chosen for the system, and the prosodic variation that will be supported by the system, how such prosodic variation will be predicted from input text must next be determined. Early TTS systems tended to develop hand-built rule systems to predict prosody assignment based on simple part-of-speech features or more elaborate syntactic parsing. The main limitation of hand-built rule systems has been the difficulty of extending and maintaining them: New rules introduced to address perceived 'errors' in prosody assignment often have unforeseen and undesirable consequences. Also, the use of syntactic parsers has generally been limited by the limits of parser speed and accuracy.

Hand-constructed rule systems for TTS prosody assignment now have largely been superceded by corpus-based techniques, in which relatively large spoken corpora are hand labeled for prosodic features and used as training material for machine learning algorithms, which produce decision procedures automatically based on textual analysis that can also be performed automatically. Typical features used in such corpus-based approaches include the part-of-speech of words in the input, the distance of words from the beginning and end of an utterance, and so on. Automatically derived decision procedures are typically limited by the amount of hand-labeled data available for training, which has led to various attempts at speeding up hand labeling, or dispensing with it altogether, by asking native speakers to assign the prosody they might use if they uttered the sentence they are being asked to label to that sentence.

Automatically derived procedures are also difficult to correct, if 'errors' in their assignment are identified, without simply providing 'correct' examples in sufficient quantity in the training corpus to outweigh the data that have led to undesirable prediction.

Machine learning approaches to accent prediction for TTS have typically used automatic part-of-speech tags (often including the part-of-speech of items in a window around the word whose accent status is to be predicted), distance of the word from the beginning or end of the sentence, and location of punctuation near the word to achieve fairly good performance ($\geq$70% accuracy when tested on labeled human data). More ambitious systems have attempted to identify the word's information status (given or new, contrastive or not) or special constructions, such as complex nominals, preposed modifiers, and discourse markers. Some recent success has been had by including word frequency and mutual information scores into the mix. Still more ambitious systems have been proposed for concept (message)-to-speech systems, in which syntactic, semantic, and discourse information is available during the generation process. However, to date these have not improved over prosodic assignment in text-based systems, largely because the correlation between prominence and other prosodic features and other linguistic information is still not well enough understood to permit more accurate prediction.

Like prominence assignment procedures, phrasing assignment in TTS systems is done either by rule or by corpus-trained procedures. Early phrase prediction in TTS systems relied on spotting key words or punctuation to determine prosodic boundary location: So, this sentence would be produced by a TTS system as two prosodic phrases due to the presence of a comma after 'so'. However, text punctuation is too sparse and often too erratic to rely on entirely for the insertion of natural-sounding phrase boundaries, especially for very long sentences. Also, some punctuation should not signal a major phrase boundary (e.g., *He comes from Little Rock, Ark.*). More sophisticated phrasing prediction procedures have been developed by hand or via machine learning techniques, as discussed previously for prominence decisions. Hand-built rule systems tend to rely on syntactic information produced by a parser, whereas automatically trained techniques tend to rely on simple part-of-speech windows, sentence length, distance of the potential phrase boundary from the beginning and end of the sentence, sentence type (question or declarative), and punctuation. However, some success has been had in recent years by incorporating more sophisticated constituent information together with these simpler features. The intuition behind the correlation of prosodic phrasing and syntactic structure is that boundaries may tend not to occur internal to certain constituents and to divide other constituents from one another. Dynamic information about prior prosodic decisions also represents an important area for future study since, for example, it is less likely that a phrase boundary will appear very soon after a previous boundary; similarly, corpus-based analysis has shown that phrase boundaries occur rarely between two deaccented words. State-of-the-art performance in prosodic phrase prediction is generally reported to be in the low to mid–90s for precision compared to a labeled test corpus.

User-Specified Control of Prosodic Variation

With some degree of explicit user control over prosodic variation, TTS can sound much more natural. This control is accomplished by providing explicit markup capabilities such that users may specify, by script or by hand, how various prosodic parameters should be set for any input text. Systems currently provide this capability via system-specific markup languages. However, markup standards are being adopted gradually that permit some general forms of prosodic control. The most popular of these currently appears to be SABLE, which has been implemented in the Festival TTS system and in the Bell Labs TTS system. Earlier markup languages that contributed to the development of SABLE were JSML (Java Speech Markup Language), SSML (Speech Synthesis Markup Language), and STML (Spoken Text Markup Language). The main limitation of these languages is that they must be mapped to the proprietary languages that existing systems provide, which commonly provide greater prosodic control than the conventional markup language. Until systems begin to be developed for standard markup languages (and until these markup languages include more fine-grained control over prosodic variation, which will involve major agreements on how to define and specify that variation), this dichotomy will remain a problem.

There is considerable practical wisdom indicating that if a TTS system is targeted at a particular application, prosodic and other features can be tuned to this application with good effect. For example, a NYNEX experiment involving a reverse telephone directory showed that the worst performing TTS system could become the most successful by modeling the prosodic behavior of the human attendants whose role was being assumed by the TTS system. In general, if the input to a TTS system is characterizable in advance (e.g., names and addresses,

automobile reservations, and a financial domain) scripts can be devised to use these assumptions to improve performance.

Evaluation

Evaluating TTS systems in general is extremely difficult. Now that most systems are quite intelligible, most testing centers on their naturalness, which is both difficult to define for raters and difficult to attribute to different components of the system. Evaluating algorithms for prosodic assignment has generally been done either through subjective judgment ratings, in which raters may be asked to judge the naturalness of a synthesized sentence with prosodic assignment done by the algorithm under consideration or by some alternate procedure. Or subjects may be asked which of two synthesized utterances they prefer, where prosodic assignment was done in two different ways. Unfortunately, prosodic assignment may interact in unpredictable ways with other components of the system: For example, if the prosodic assignment component correctly specifies that a yes–no question contour be used but the database cannot produce such a contour, the prosodic assignment component may be poorly evaluated in such tests. Assigning 'blame' to various components is in general quite difficult since small failures in components may contribute to a lack of naturalness.

A more objective, but still flawed, approach is to evaluate the prosodic assignment procedure's automatic specification on a hand-labeled test set of human speech. There are always multiple ways of producing any utterance, however. Thus, comparison of TTS output to any single prediction would appear to be too strict a metric. However, it is not clear what kind of comparison to human performance would be more valid. Some have compared their prosodic assignment to the combined production of multiple speakers, but this has clear drawbacks. For example, allowing a phrase boundary in a given sentence wherever one of multiple human speakers produces a boundary can easily result in a sentence with far too many boundaries for any human production. Also, the location of one boundary may depend on the presence of another, so a production including only one may sound distinctly odd. Task-based evaluations have also been attempted with some success, as in the reverse telephone directory evaluation mentioned previously, in which subjects were asked to transcribe the names and addresses the system produced; a TTS system with worse overall intelligibility performed better than other systems when its prosody was changed to model that of the human attendant. However, this modification largely involved simply slowing the rate of the synthesizer. In summary, the evaluation of TTS systems in general, and of prosodic assignment in particular, remains a major research question.

Conclusion

In the current age of corpus-based TTS systems that rely on searching a large inventory of speech for variable-length units to concatenate, with relatively little system modification of prosodic features, effective and realizable prosodic assignment represents a major problem. There are many issues to be resolved regarding how natural-sounding prosody can be assigned, based on text input or even on more information-rich representations. However, if such prosodic variation is not actually possible within a TTS system without degrading the overall quality of the modified speech, the field has a serious problem. Therefore, not only must there be research on how to assign prosodic features more effectively (particularly full pitch contours) but also the overall architecture of the system must make it possible to realize such prosodic assignment in the output speech. Some very natural-sounding systems still cannot produce yes–no question intonation reliably, for example, because too few question contours occur in the system database.

Speech Technologies: Language Variation

S King, University of Edinburgh, Edinburgh, UK

© 2006 Elsevier Ltd. All rights reserved.

Introduction

This article deals only with the sources and types of variation in speech that affect speech technology systems such as ASR and TTS. A companion article (*see* **Handling Variation in Speech and Language Processing**) looks at how such systems attempt to deal with this variation. Because this article is therefore largely a survey of well-understood linguistic phenomena, almost all the references will be to separate articles in this encyclopedia (*see* **Handling Variation in Speech and Language Processing; Natural Language Processing: Overview; Speech Recognition: Statistical Methods**).

Speech Recognition

Automatic speech recognition (ASR; *see* **Speech Recognition: Statistical Methods**) usually means the conversion of speech waveforms into sequences of words (i.e., text), and does not usually imply any further syntactic (*see* **Parsing: Statistical Methods**) or semantic (*see* **Natural Language Understanding, Automatic**) processing of this text, such as might be necessary in a spoken dialog system (*see* **Computational Language Systems: Architectures**).

Most modern ASR systems have a common architecture. The speech waveform is invariably preprocessed into a sequence of vectors (called feature vectors), each representing the short-term spectral envelope of a section of waveform. Then, a hierarchy of statistical models, usually consisting of a model of word sequences – the language model, usually an n-gram model – a word-to-phone model – the pronunciation lexicon (*see* **Computational Lexicons and Dictionaries**) – and models of phone-sized units of speech – usually hidden Markov models (HMMs) (Huang *et al.*, 2001) – is used to determine the most probable word sequence. Statistical models outperform alternatives, such as rule-based or example-based systems. In the case of HMMs, this is because they are able to learn, from data, not only the average value of the feature vectors associated with a particular unit of speech but also the variation about this average. HMMs are trained on large quantities (several hundred hours) of transcribed speech data and N-gram models are trained on very large quantities of text (e.g., more than 100 million words).

Given a good enough model and sufficient quantities of appropriate training data, statistical models are able to generalize: They can recognize new speech data with word sequences never seen during training. However, when presented with speech that differs too greatly in some respect from the training data, the accuracy can drop dramatically. Understanding the types, sources, and acoustic consequences of variation in speech is therefore important to the developers of ASR systems.

In the early development of ASR systems (*see* **Speech Recognition, Automatic: History**), the focus was on transcription of 'read text' because the primary application of the technology was thought to be dictation machines. More recently, interest has shifted to processing spontaneous speech as found in dialog (whether between humans or between humans and machine). Challenging problems currently under investigation include the transcription of spontaneous telephone conversations, rich transcription' of speech, transcription and annotation of multiparty meetings, and the searching of speech databases (*see* **Spoken Document Retrieval, Automatic**).

Speech Synthesis

The conversion of plain text (such as the paragraph you are reading now) to speech waveforms is known as text-to-speech (TTS) (*see* **Speech Synthesis**). When more information about the text is available (such as the correct syntactic structure or semantic information such as which information is given and which is new in a particular utterance), the task is then sometimes called concept-to-speech. This extra information will be available if the text was automatically generated. Clearly, TTS is the harder problem because any syntactic, semantic, or pragmatic information required by the system must be inferred from the text. This is usually achieved with a combination of rules and statistical models (Jurafsky and Martin, 2000) Most TTS systems construct the synthetic speech waveform using fragments of speech taken from a database of recorded natural speech (from a single speaker); these systems are known as concatenative.

The variability and ambiguity in text can present problems for TTS systems in two ways. First, a single sentence taken out of context will often appear to have more than one 'correct' reading; resolving this ambiguity requires contextual information, which may be available in the preceding sentences or may require knowledge beyond that contained in the text (world knowledge). Typical TTS systems have very little world knowledge. Second, the rules and statistical models used in typical TTS systems are usually optimized or trained on some data set; but,

however large it is, this data set cannot cover all possible words and phrases that will be encountered when running the system. So, just as for ASR, a TTS system must be able to generalize from limited training data.

Other Speech Technologies

As well as recognizing it and synthesizing it, there are other interesting and useful things we can do with speech.

When transmitting speech down a long-distance telephone cable or through the airwaves to and from mobile phones, it is usual to code the speech. This coding achieves both substantial compression (a lower data rate than the original waveform) and robustness to errors introduced by the channel. The coding is usually specifically designed for speech; for example, it might take advantage of a source-filter model and code the source and filter components separately. Because a model of speech is being used (however simplistic), there are potential problems with variation, particularly across speakers.

In voice transformation (also known as voice morphing), the speech of one speaker is manipulated to sound like another speaker (*see* **Voice Modification, Synthetic**). Applications include speech synthesis and film dubbing. Clearly, understanding the factors that make one person's speech differ from another's is crucial when performing voice transformation.

Both ASR and TTS are required for a spoken language dialog system. In such a system, some form of speech understanding must be implemented (*see*). If this involves parsing the input, then the differences between spoken and written language must be taken into account because most parsers are developed for written language only.

Differences between speakers are not always a problem. In the task of speaker recognition, these differences are used to identify, or verify a claimed identity of, the speaker (*see* **Speaker Recognition and Verification, Automatic**).

Variations in the Speech of a Single Speaker

No speech sound is ever produced in precisely the same way twice, even by a single speaker; the dimensions along which we can describe, and perhaps quantify, this variation include the speech production processes and the speaking rate.

Speech Production Processes

We can divide variations in the speech production process into two distinct categories. The first consists of systematic variations due to phonetic context, including allophonic variation and co-articulation; the second category consists of random variations.

Allophonic variation is the systematic variation in the acoustic realization of a phoneme depending on the phonetic context. Examples are that a stop may be released in some situations but not in others (such as before another stop) and that /l/ in English may be realized differently in syllable-initial versus syllable-final positions (light vs. dark). Clearly, such systematic variation should be accounted for in ASR (e.g., by using a different HMM for each type of /l/) and in TTS (by synthesizing the appropriate /l/ in each context).

Co-articulation is the variation in underlying articulator movements depending on context, both left and right. The following example illustrates the process of assimilation (*see* **Assimilation**) in which the [n] has assimilated to the place of articulation of the following bilabial stop [b], thus changing from an alveolar [n] to a bilabial [m].

[hænd]	+	[bæg] →	[hæmbæg]
hand		bag	'hambag'

The [d] has also been deleted. These processes must be realized in TTS and accounted for in ASR. Cross-word effects such as these cannot be handled in the lexicon.

The second category of variation is random changes. These arise because the motor control system of the articulators is imperfect (we cannot exactly repeat an articulatory gesture). Human speech perception has no problem with the acoustic consequences of small random changes because they do not cause categorical changes (*see* **Speech Perception**). Because these changes are not predictable, in ASR they must be left to the low-level statistical component (usually a mixture of Gaussian distributions) to deal with. In TTS, including these variations in the synthetic speech may improve naturalness.

Speaking Rate

At higher speaking rates, the processes just mentioned have an increasing effect on the speech produced. Co-articulation becomes more pronounced and the frequencies of deletions, disfluencies, and mispronunciations all increase.

Differences between Individual Speakers

The speech of two speakers of the same language will exhibit systematic differences that are not attributable to external factors.

It is common in speech technology to make use of the source-filter model (*see* **Phonetics, Acoustic; Speech Production**), which divides the speech production process into two components: the source (e.g.,

the vocal folds for voicing) and the filter (the vocal tract). This model is somewhat simplistic, but it is widely used in speech technologies and it is useful in understanding cross-speaker variation.

Differences in vocal tract geometry, particularly in length, cause shifts in the formant space; a shorter vocal tract (e.g., in female speakers compared to male speakers of the same age or children compared to adults) produces higher formant frequencies. Because the acoustic features used in ASR systems represent the spectral envelope (an approximation to the vocal tract frequency response), the features extracted for different speakers will vary systematically.

The range of F_0 (the rate of vibration of the vocal folds, whose perceptual correlate is pitch) varies across speakers, too. This creates challenges for some ASR systems and all TTS systems. In ASR of non-tone languages, F_0 is almost always ignored; however, in tone languages, where F_0 carries segmental information, it is necessary to model F_0; this raises the problem of normalizing across speakers: one Cantonese speaker's low-rising tone might have a very similar F_0 contour (in both absolute value and in shape) to another speaker's mid-rising tone (*see* **Tone: Phonology**).

The vocal folds (*see* **States of the Glottis**) are also largely responsible for voice quality (*see* **Voice Quality**). In model-based TTS (*see* **Speech Synthesis**), this means a detailed model of the vocal-fold behavior is necessary to capture the individual qualities of any real speaker. In voice transformation (*see* **Voice Modification, Synthetic**), conversion of this aspect of speech is critical.

Variation in Situation

Speakers change many aspects of their speech, both consciously and subconsciously, in response to situational factors.

- Planned versus spontaneous speech. There are important differences between read text (e.g., that of a newscaster), carefully planned speech (e.g., from an experienced public speaker without notes), and spontaneous speech (e.g., a conversation).
- Effect of the listener on the speaker. Studies of human-human dialogue, such as those of the Maptask corpus (Anderson *et al.*, 1991), have been used to discover the effects of speaker familiarity and eye contact between speakers. Other factors that affect speakers include their relationship to the listener (their child, their boss, etc.). Interestingly, when speakers know the listener is a machine, they are more likely to adapt their speech (to become more careful) than if they believe they are talking to a human. This has implications for spoken dialog system designers: if the system is so good that users believe it is a human (*see* **Turing Test**), their speech is more likely to be problematic for the ASR component.
- Disfluencies and related phenomena. Word fragments, repeated word or phrases, and repairs cause problems for ASR systems. Because ASR systems almost always see speech as a string of words to be transcribed and use a simple N-gram model of language, the insertion of non-words or word fragments into the word string causes problems. Should they be transcribed? Can they be treated as real words? How do they affect the language model? (*see* **Handling Variation in Speech and Language Processing**, which considers these questions.) Hesitations and filled pauses are not always speech errors; they may be used by speakers, particularly in dialog, to perform functions such as holding the current turn.
- Dialog versus monolog. In dialog speech (or speech between two or more speakers), there are significantly more disfluencies than in monolog. Speakers overlap their speech significantly; in a small meeting situation, we may find that as many as half of all utterances overlap. Even when recording the speech with close-talking head-mounted microphones, it is very difficult to obtain separate acoustic signals for each speaker. This presents a major challenge for speech recognition systems.

Variations within a Single Language

All languages with large numbers of speakers contain subgroups: accents (*see* **Accent**) and dialects (*see* **Dialect Atlases**).

Variations among different accents include systematic and idiosyncratic changes in word pronunciations. For example, accents of English can be divided into rhotic and nonrhotic varieties. Speakers with rhotic accents (e.g., Scottish English and most accents of North American English) pronounce the [r] at the end of words such as *nicer*, whereas nonrhotic speakers (e.g., of Southern British English) do not. In concatenative TTS systems (*see* **Speech Synthesis**) particularly, it is important for the pronunciation dictionary to closely match the speaker whose speech is being used.

Different dialects of a language can exhibit all the differences among different accents plus differences in vocabulary (*see* **Standard and Dialect Vocabulary**) and syntax. Because speech technology systems tend to be constructed for standard accents and dialects, speakers of nonstandard accents and dialects are

more likely to have difficulty using these systems. The same applies for non-native speakers.

Variations between Languages

Until recently, only a small number of languages had been used in the primary research and development of speech technology; of these, English, particularly North American English, dominated (and still does). When attempts are made to port existing systems to other languages, a number of cross-language differences must be dealt with. Some differences are minor, and the system can ported simply by replacing some of the linguistic resources (e.g., the pronunciation dictionary) or providing new training data. Other differences are more significant, and the system must be changed in a more fundamental way. Systems that must deal with more than one language may be required to automatically detect which language is being spoken (*see* **Language Identification, Automatic**).

Variations across Closely Related Languages

Phoneme Inventory Speech technology systems typically use relatively small phoneme inventories compared to the full set of IPA (*see* **International Phonetic Association**) phonemes. First, almost all systems are designed to deal only with a single language at a time, so only a subset of the IPA phonemes are required. Second, small inventories are inherently preferred. In ASR, this is because a statistical model must be built for every phoneme in every left and right context. If there are 40 phonemes and the context consists of only one phoneme to the left and one to the right, this means around $40^3 = 64{,}000$ models; with 50 phonemes, this rises to 125,000. In TTS, the typical fragment of speech used by concatenative systems is the diphone, which consists of the second half of one phone plus the first half of the following phone. Hence, the number of diphones increases as the square of the number of phonemes.

Morphology Both ASR and TTS require pronunciations for words. In TTS, only the orthographic form is available as input; any extra information required to predict pronunciation (such as part-of-speech (POS) tags; *see* **Part-of-Speech Tagging**) must be inferred by the system. This process of letter-to-sound (LTS) conversion must be automatic because new words will be encountered at runtime; for large-vocabulary ASR, (semi-)automatic methods are also desirable. For languages with productive morphology, automatic morphological decomposition (*see*) can be used to assist LTS because the pronunciations of roots and affixes can be shared across many words and combined to produce pronunciations for complete words. Languages for which morphology is commonly used in LTS include Spanish, German, and Arabic; English, for example, is too irregular. Because systems for English rarely use a morphological component, this must be added when porting to most other languages (*see* **Dictionaries and Inflectional Morphology; Morphology and Language Processing**).

Lexicon and Vocabulary Size Languages with a highly productive morphology can have very large vocabulary sizes. The standard approach used for English ASR and TTS, which is to treat words as atoms and list all (orthographically) distinct words in the lexicon, is not appropriate for such languages. In ASR for these languages, failing to make use of morphology will mean a much higher out-of-vocabulary rate (words appearing in speech to be recognized that are not listed in the pronunciation dictionary of the system).

Languages with writing systems that omit some vowels or do not mark word boundaries create additional problems for speech technologies. New modules must be added to the system to predict these missing pieces of information before words can be looked up in the lexicon.

Syntax In ASR, there is rarely a sophisticated model of syntactic structure. Language is modeled as a string of words with no deep structure, so therefore differences in syntactic structure cause no real problems, although the power of simple n-gram models will vary across languages; for example, n-gram models cannot capture long-range dependencies.

In TTS, however, some syntactic analysis is usually performed. This may be very shallow, such as part-of-speech tagging (*see* **Symbolic Computational Linguistics: Overview**), or somewhat deeper, to discover phrase boundaries, for example. In English, the relationship between traditional syntactic constituents (e.g., noun phrases and verb phrases) and prosodic structure (*see* **Prosodic Aspects of Speech and Language**) is via semantics (*see* **Semantics of Prosody**), so even a deep syntactic analysis is not sufficient. One theory of syntax, Combinatorial Categorical Grammar (CCG) (*see* **Combinatory Categorial Grammar**), is able to generate constituents that better match the information structure, and therefore the prosodic structure, of utterances.

Variations across Distantly Related Languages

When we move to more distantly related languages, further problems are encountered.

Differences in Acoustic Features Tone languages use F_0 to make segmental distinctions. A speech recognition system for a non-tone language will generally not use F_0 information, so it is when ported to a tone language, the front end of the system, which extracts salient acoustic features from the waveform, will need to be modified.

Languages without Existing Linguistic Resources For some languages, there are few or no existing resources, such as large amounts of text data in electronic form or pronunciation dictionaries. These resources must be created, and this is one of the largest barriers to use of speech technologies for these languages. Projects such as the Local Language Speech Technology Initiative (Tucker, 2004) are addressing this problem.

Differences between Spoken and Written Language Even widely spoken dialects of major languages may lack linguistic resources. For example, Levantine Arabic (Arabic, Levantine Bedawi Spoken) is a spoken dialect of Arabic. Because writing in dialect is stigmatized, written Arabic is almost exclusively Modern Standard Arabic, which is significantly different (being a modernized version of Classical Arabic).

Nonlinguistic External Factors

A number of factors can modify speech signals on the way from the speaker to speech technology system.

Transmission Factors

Telephone Speech Telephone networks generally limit the bandwidth of the speech signal they carry (typically limiting the range of frequencies present in the signal to 300–3500 Hz). This reduces the amount of information available to ASR systems. For many male speakers, this also means that the first harmonic (sometimes called the fundamental) of F_0 is lost. Human listeners are able to infer F_0 from the spacing of the remaining harmonics.

Digital channels (which include most mobile and long-distance channels) impose degradation on the speech signal due to the coding and decoding of the signal (Gold and Morgan, 1999). Mobile telephones are frequently used in noisy (e.g., in cars) and reverberent (e.g., in subway stations) environments.

Microphone Different microphones can have surprisingly large effects on the speech signal, to the extent that ASR accuracy can be severely reduced when the microphone used in testing is different from that used to collect the training data.

Environmental Factors

Even before the speech reaches the microphone, it can be corrupted.

Acoustic (Background) Noise A particular problem of far-field microphones (e.g., desk-mounted vs. head-mounted) is the higher level of background noise relative to the speech signal.

Reverberent Environments When multiple paths between speaker and microphone are present (e.g., because of reflections from walls), the signal received by the microphone contains not only the direct-path signal but also weaker, delayed versions. This blurs the information across time and can cause significant degradation in speech quality. In making recordings for concatenative TTS systems, great care is taken to avoid recording these reflected signals (by using a recording studio or anechoic chamber). Far-field microphones also pick up a higher level of these reflected signals than close-talking microphones relative to the direct-path speech signal.

Speech: Biological Basis

D H Whalen, Haskins Laboratories, New Haven, CT, USA
B Lindblom, Stockholm University, Stockholm, Sweden

© 2006 Elsevier Ltd. All rights reserved.

The biological basis of speech has three main components: the physiology of the vocal tract, the physiology of the perceptual system (primarily the ear but also the eye and, occasionally, other systems), and the neural resources that allow their use for communication. The genetic underpinnings of these functions are beyond the scope of this article, so the functional aspects will be discussed.

Speech, like language, is a biological system (Liberman and Whalen, 2000). Because it is the part of language with a physical realization, the immediacy of the biology is more apparent than it is for syntax and semantics, but it forms a part of that complete biological system. Language is generally considered the defining characteristic of humans, and it will develop in every neurologically normal child with virtually any exposure to linguistic material. The large investment that is made in being able to acquire and use language is justified by the immense rewards for using it, and the severe penalties for being unable to.

Evolution of Speech

Speech clearly evolved for, and presumably along with, language. Even though it is a system that has no clear counterpart in the animal world for its complexity in serving communication, it is, like the elephant's trunk (equally unique in its way; cf. Pinker, 1994), derived from previous capacities. There are some aspects of signaling systems in other animals that are similar to language (*see* **Animal Communication: Overview**; **Animal Communication Networks**), but little that resembles speech. The various sounds made by chimpanzees and other primates are clearly related to some of the sounds used in speech. These include hoots, calls, lip smacking, barks, etc. Gelada baboons are capable of vowel-like vocalizations very similar to the human vowels /a i u/ (Richman, 1976).

One of the most interesting signaling systems in primates is that of the vervet monkeys. They use three distinct alarm calls: short tonal chirps to indicate the presence of a leopard; a high-pitched chatter to signal a python; and a low-pitched staccato grunt to signal an eagle (Seyfarth *et al.*, 1980). The restriction of this signaling system to a small set of messages limits its usefulness in a way that is overcome in speech by the Particulate Principle (Studdert-Kennedy, 2000): language makes use of small, meaningless components (phonemes) that recombine in multiple ways to create meaningful units (morphemes). The size of the vocabulary, therefore, is a multiplicative function of the number of units, unlike a system in which each message needs a separate signal. Only with this feature can spoken language be as powerful as it is.

Speech is presently the primary medium for language in most communities, but sign language is a strong and equally complex alternate system (Emmorey, 2002; Klima and Bellugi, 1979). Thus, there is the possibility that a manual system of communication may have preceded the oral version; this topic will continue to be debated. Given the amount of use humans make of language, it is surprising how little evolutionary change was needed for it. The entire production system, from the lungs to the lips, makes use of structures that are used for other purposes as well: breathing, chewing, kissing. The most notable changes in the physiology are a lower resting position of the larynx in adults, a complex larynx, a more highly innervated tongue, and a bend in the vocal tract that allows for efficient creation of various linguistic sounds. The main bone that is involved in these changes is the hyoid bone, which has come to be connected to other bones only by cartilage to facilitate fine adjustments in the larynx. Since the hyoid bone is not tightly connected to other bones, its position cannot be reliably determined in fossil deposits. Only indirect evidence is available from the archaeological record for changes in this bone.

© 2006 Elsevier Ltd. All rights reserved.

The biological basis of speech has three main components: the physiology of the vocal tract, the physiology of the perceptual system (primarily the ear but also the eye and, occasionally, other systems), and the neural resources that allow their use for communication. The genetic underpinnings of these functions are beyond the scope of this article, so the functional aspects will be discussed.

Speech, like language, is a biological system (Liberman and Whalen, 2000). Because it is the part of language with a physical realization, the immediacy of the biology is more apparent than it is for syntax and semantics, but it forms a part of that complete biological system. Language is generally considered the defining characteristic of humans, and it will develop in every neurologically normal child with virtually any exposure to linguistic material. The large investment that is made in being able to acquire and use language is justified by the immense rewards for using it, and the severe penalties for being unable to.

Evolution of Speech

Speech clearly evolved for, and presumably along with, language. Even though it is a system that has no clear counterpart in the animal world for its complexity in serving communication, it is, like the elephant's trunk (equally unique in its way; cf. Pinker, 1994), derived from previous capacities. There are some aspects of signaling systems in other animals that are similar to language (*see* **Animal Communication: Overview**; **Animal Communication Networks**), but little that resembles speech. The various sounds made by chimpanzees and other primates are clearly related to some of the sounds used in speech. These include hoots, calls, lip smacking, barks, etc. Gelada baboons are capable of vowel-like vocalizations very similar to the human vowels /a i u/ (Richman, 1976).

One of the most interesting signaling systems in primates is that of the vervet monkeys. They use three distinct alarm calls: short tonal chirps to indicate the presence of a leopard; a high-pitched chatter to signal a python; and a low-pitched staccato grunt to signal an eagle (Seyfarth *et al.*, 1980). The restriction of this signaling system to a small set of messages limits its usefulness in a way that is overcome in speech by the Particulate Principle (Studdert-Kennedy, 2000): language makes use of small, meaningless components (phonemes) that recombine in multiple ways to create meaningful units (morphemes). The size of the vocabulary, therefore, is a multiplicative function of the number of units, unlike a system in which each message needs a separate signal. Only with this feature can spoken language be as powerful as it is.

Speech is presently the primary medium for language in most communities, but sign language is a strong and equally complex alternate system (Emmorey, 2002; Klima and Bellugi, 1979). Thus, there is the possibility that a manual system of communication may have preceded the oral version; this topic will continue to be debated. Given the amount of use humans make of language, it is surprising how little evolutionary change was needed for it. The entire production system, from the lungs to the lips, makes use of structures that are used for other purposes as well: breathing, chewing, kissing. The most notable changes in the physiology are a lower resting position of the larynx in adults, a complex larynx, a more highly innervated tongue, and a bend in the vocal tract that allows for efficient creation of various linguistic sounds. The main bone that is involved in these changes is the hyoid bone, which has come to be connected to other bones only by cartilage to facilitate fine adjustments in the larynx. Since the hyoid bone is not tightly connected to other bones, its position cannot be reliably determined in fossil deposits. Only indirect evidence is available from the archaeological record for changes in this bone.

The lower resting position of the larynx is evidently ideal for speech, since the larynx is typically lowered for phonation in all animals (Fitch, 2002). It was previously thought that the descended larynx was peculiar to humans (Lieberman, 1984), but recent ethological work has found a similar configuration in other animals, such as the red deer (Fitch and Reby, 2001). In those animals, the function of the descended larynx appears to be that of signaling a larger body size than the animal actually has; during phonation, the larynx is pulled below its resting point, almost to the sternum in some cases. In humans, the function appears to be more tied to ease of articulation, because both males and females lower their larynges. Articulation benefits both in terms of having the larynx near the level necessary for nonnasal phonation (rather than having to lower it as with most other animals; Fitch [2000]) and for enhancing the bend in the vocal tract that allows for a wider range of speech articulation. The extra lowering that occurs in males at puberty may also be in the service of signaling a larger size (Ohala, 1984). Thus, it is likely that the lower resting position of the larynx was achieved after speech was in common use (Whalen, 2002).

The evolution of the larynx, important as it is for the kind of control we see in modern speech, is difficult to assess from the fossil record. The cricoid and thyroid cartilages contain and control the vocal folds, but all three of these structures fail to leave fossil traces. Thus there is indeterminacy here as well.

The development of a flexible tongue was also important. Since greater control of this structure implied more complex innervation, one hypothesis was that the size of the hypoglossal canal (which allows the nerve controlling the tongue to exit the skull) relative to the size of the skull would indicate when this control appeared in evolution (Kay *et al.*, 1998). Later work showed that that there was a great deal of overlap between modern humans and other primates and that the nerve itself could vary in size without any apparent increase in control (for chimpanzees and orangutans). Thus, the timing of this change cannot be determined from the fossil record.

There is less change in the perceptual system specifically for speech than there is in the production system. The auditory pathway is undifferentiated for speech until the cortical level, and our range of hearing, though well suited for the range of sounds used in speech, is not extraordinary among mammalian systems. Whatever evolution took place in service of speech perception, then, is primarily neurological.

Evidence for the evolution of the brain itself is limited largely to studies of brain size and to ethological comparisons with close and distant relatives of humans. Primates have increased in size over the past four million years, but the line that led to modern humans increased brain size more rapidly than expected. Observations of species from mice to elephants are generally predicted by $E = k \times W^{2/3}$ (E = brain weight, W = body weight, k = constant). Apes, hominids, and humans have larger brains than predicted by that rule (Tobias, 1987). Plotting the difference between the actual weight of a primate's brain and E, the equation-based estimate, versus evolutionary time, produces a curve that increases over time. Recent work has shown that this overencephalization is present in the equid line as well (Henneberg, 1998), and that the most recent changes may be due to a decrease in body weight due to a streamlining of the digestive system (Henneberg, 1998). Brain size itself is not a clear indicator of language use, especially since other activities – tool making, hunting, other aspects of culture – were also presumably becoming more complex throughout hominid evolution. Language is generally assumed to support those activities, so the greater-than-expected growth in brain size is likely to be intricately linked with elaboration of the entire range of activity.

Language and speech are primarily lateralized to the left hemisphere of the brain (Branch *et al.*, 1964; Broca, 1865). This is less true for left-handers than for right-handers, and women appear to be more bilateral in their processing than men (Pugh *et al.*, 1996). When competing speech sounds are presented to both ears, those at the right ear are perceived more reliably than those at the left, because the strongest cortical connections for the ears are contralateral (Shankweiler and Studdert-Kennedy, 1967). The reasons for this effect and its time depth are still undetermined.

Human speech can be mimicked by various animals, but this does not indicate a use of language. The most successful mimics are parrots, although claims have also been made for Hoover the talking seal and even dogs and horses. All of these creatures use a vocal tract that is radically different from humans, and so the control must be quite different. Parrots, for example, use their tongues to modulate the signal but also appear to match their fundamental frequency to their most prominent resonance, an articulatory maneuver used only by sopranos in their highest range (Beckers *et al.*, 2004; Patterson and Pepperberg, 1998). Pepperberg (1999) has made stronger claims for the language use of her trained parrots, yielding one of the most convincing examples of word use by animals (Anderson, 2004: 303).

Speech Production

Speech is produced by coordinated action of the lungs, larynx, jaw, tongue, velum, and lips (*see* **Speech Production**). As mentioned, each of these organs contributes to other functions, ranging from the necessary (breathing) to the aesthetic (singing). The neural control of the vocal system is quite complex and is generally separate from that of the other functions. There is a different coupling of muscle activations for chewing than for speech (Moore *et al.*, 1988); chewing is even dissociated from babbling (Moore and Ruark, 1996). This calls into question theories that propose that speech arose out of nonspeech gestures (MacNeilage, 1998). Speech is not only biologically special (unique to humans), it is specialized as well (innervating the same muscles differently depending on whether speech function is involved or not).

For humans, unlike other primates, vocalization is under cortical control. Other primates primarily initiate their vocalizations subcortically and thus have no control over the form of most their vocalizations, though they are able to control some (Jürgens, 1998). Humans have volitional (though usually not conscious) control over every aspect of the speech production process, from breathing up through articulation. The breathing patterns for speech are quite different from those of tidal breathing, with very short intakes and long exhalations, under active control (Lenneberg, 1967; MacLarnon and Hewitt, 1999). The lungs are elastic, like a balloon, so that pressure is generated by this elasticity itself, promoting exhalation. During speech, the chest cavity is held outward to slow the escape of the air (Winkworth *et al.*, 1995); those same muscles can contract to increase pressure, especially as volume decreases.

The larynx provides the voiced source for speech, creating a periodic source by the alternating closure and opening of the vocal folds. The rate of alternation is the fundamental frequency of a sound and is governed by the rate of air flow, the stiffness and density of the folds, and other adjustments in the vocal tract. The cycling movement of the vocal folds is an aerodynamic phenomenon due to elasticity of the folds and variations in air pressure: the folds are forced apart by subglottal pressure, then drawn back together, according to the Bernoulli principle, due to reduced pressure in the air rushing through the glottis.

Speech sounds are overlapped in their production, resulting in coarticulation (e.g., Fowler, 1980; Liberman *et al.*, 1967). This allows for more efficient use of the sound stream but results in an acoustic signal that is highly context dependent. The perceptual system, having evolved in concert with the production system, is prepared to deal with this coarticulation, a fact that has been dubbed 'parity' between the two systems (Liberman and Mattingly, 1985). Rather than treating the context dependence as noise to be overcome, the perceptual system treats virtually all of it as information about the production process.

Neurologically, the area most clearly involved is Broca's area (Brodmann area 44/45), which is essential to voluntary articulation. Motor, premotor, and anterior (insula) areas are involved as well; the cerebellum is involved in fine-tuning the timing of speech. Although recent neural imaging techniques have improved our ability to examine the brain during various tasks, studying speech production is difficult since the movement of the articulators tends to move the head as well, making alignment of the images problematic. Event-related fMRI allows us to overcome this limitation to some extent, but the results so far have been somewhat inconclusive about the exact network of systems that is responsible for speech production. Future refinements should improve our models.

Speech Perception

Speech is primarily perceived through the ear, but the eye has a contribution to make as well (McGurk and MacDonald, 1976; Sumby and Pollack, 1954); both sensory systems, of course, are ultimately represented in the brain. The sense of touch can also be employed, primarily for the deaf, either through the Tadoma method of training (Schultz *et al.*, 1984) or through prosthetic devices that transduce part of the speech signal (Galvin *et al.*, 1999). The integration of the various sensory modalities indicates that speech is flexible enough to be sensitive to a variety of atypical means of presenting the underlying dynamics of the signal (Fowler and Dekle, 1991).

The first challenge that the perceiver faces is discovering whether the acoustic signal contains speech at all. Since language is seldom produced in a completely quiet environment, the listener must sort out what is speech and what is noise or other signals. Some theorists propose that this is done by 'scene analysis' in which the acoustic energy received is allocated to various perceptual categories or streams (Bregman, 1990). However, there are various conditions under which listeners do not follow this sensible path. In duplex perception, part of a syllable is presented to one ear and part to the other. Even though the listener clearly perceives two streams (one at each

ear), the speech information is nonetheless put together into a single speech percept, with a nonspeech percept remaining at the other ear (Rand, 1974; Xu *et al.*, 1997). An even more difficult challenge is found in sinewave speech (Remez *et al.*, 1981), in which the first three resonances that constitute most of the speech information are replaced with time-varying sinusoids. Even though no one perceives this as natural speech, most listeners come to hear the speech it was modeled on, even though the signals obey virtually none of the grouping principles of scene analysis (Remez *et al.*, 1994).

The speech signal is difficult to parse even when identified as such, since there are very few indications of segments in the acoustic stream. The ear can identify and sequence about seven different events per second, but phonemes are conveyed at rates of 15 per second or more. As mentioned in the production section, this is accomplished by overlapping the production so that the coarticulated signal can convey the message more efficiently. This 'encoding' of the signal allows humans to communicate well (Liberman *et al.*, 1967) but creates challenges for machine recognition. Because the perceptual system is expecting context-conditioned variation, it parses the signal so that the perceived linguistic message is close to the original message intended by the speaker. Some theorists have proposed instead that there is a relational invariance in the signal; in particular, Landmark Theory (Stevens, 2002) proposes that regions around major spectral or amplitude change are compared and features extracted from that comparison. Research is continuing to determine whether this conceptualization will produce more accurate automatic recognition and whether it will explain human perception.

Neurologically, the acoustic signal enters the cortex through the primary auditory cortex. From there, it radiates primarily to the posterior superior temporal gyrus (including Wernicke's area [Brodmann 22, along with 39 and 40]). There is evidence for the involvement of motor areas (Wilson *et al.*, 2004). If there is integration with a visual signal, it appears to be supported by a variety of areas (superior temporal sulcus, premotor cortex, and cingulated gyrus, among others; Calvert and Thesen, 2004). Lip reading also induces activation in primary auditory cortex (Calvert *et al.*, 1997). As with production, our ability to assess the entire system with current tools is limited.

Links between Production and Perception

Throughout history, the vast majority of speech has been heard in the immediate vicinity of the speaker. Thus, there was no great impetus for thinking that there might be something unrelated about speech production and perception: the producer is there, so what is perceived is what is produced. However, with the advent of recording devices, it became possible to separate the acoustic signal from the speaker, suggesting that there might be no essential link between the two processes. The invention of the sound spectrograph during World War II led to an enhanced view of the acoustic structure of speech (Potter *et al.*, 1947), further enabling a dissociation between the two processes. This has led to a robust debate in the literature that is still not settled.

For proponents of acoustic theories, that is, those who propose that there is no essential link between production and perception, the fact that the acoustic signal is perceived accurately indicates that only acoustics are needed. Prototypes of phonetic categories are presumed to arise during language acquisition, and sounds are matched to these prototypes (Diehl and Kluender, 1989; Diehl *et al.*, 2004; Guenther *et al.*, 1998; Stevens, 2002). These theories also generally posit that there is nothing special about the processing of speech sounds and that they are perceived by general auditory processes. The categories are necessarily linked to production at some point, since listeners are also speakers, but it is presumed to be a cognitive link.

Other theories of speech perception assert, instead, that there is an immediate and necessary link between the objects of speech production and perception, notably the Motor Theory (Liberman *et al.*, 1967; Liberman and Mattingly, 1985) and direct realist theories (Best, 1995; Fowler, 1986). Here, the parity between speaker and listener is a given since the objects of both are linguistically significant movements of the vocal tract, or 'gestures.' Recovery of gestures is achieved by a specialization (in Motor Theory) or by general processes that are attuned to the distal object (in direct realist theories). Gestures are assumed to be perceived by means of all their attributes, both the usual ones of sound and vision and the unusual ones such as touch (Fowler and Dekle, 1991).

Imitation, especially by infants, reveals a critical role for linking perception of certain actions and production. Although it is possible to envision a system that establishes links between categories (perceptual and productive) in adults, it is hard to see how it is that infants are able to map what they hear onto what they do. Yet infants imitate speech from a very early age, mapping adult productions onto their much smaller vocal tract. It is difficult to see how this is accomplished on purely acoustic grounds.

One intriguing way in which production and perception have been found to be linked in monkeys is the so-called mirror neurons (Rizzolatti and Arbib, 1998). These are cells in the cortex of monkeys that are active both when the animal performs an action and when it sees that action performed (even by a human). They are located very near the homolog of Broca's area, crucial for speech. Mirror neurons have also been found for sound. There are neurons that activate both when a peanut is cracked and when just the noise of a peanut cracking is presented (Kohler *et al.*, 2002). There is a suggestion of mirror neurons at work in human speech perception in the activation of tongue muscles when listening to lingual gestures (Fadiga *et al.*, 2002).

Speech Development

Human infants are ready to learn speech. It takes major neurological disorder or a complete lack of speech input for a child to fail to learn speech. Although this indicates a genetic predisposition to use speech, the exact nature of the genetic component is still being debated. Exposure to speech actually begins before birth, as speech is moderately intelligible even *in utero* (Smith *et al.*, 2003) and some prebirth sounds seem to be remembered (DeCasper *et al.*, 1994). The mother's voice seems to be learned *in utero* (DeCasper and Fifer, 1980), indicating that the neural organization for speech perception may begin prior to birth.

Infants are not capable of producing speech, but they perceive it in interesting ways early on. They discriminate most phonetic distinctions that have been tested (Werker, 2003; Werker and Tees, 1984). These include both distinctions that are in their language environment and many that are not. By about 1 year of age, much of this sensitivity has been lost in favor of phonetic distinctions used in the ambient language. Infants treat speech as a special signal from the beginning, perceiving duplex stimuli in the way that adults do (Eimas and Miller, 1992) and preferentially listening to speech over nonspeech (Vouloumanos and Werker, 2004) even as early as 2 months of age.

Production begins with babbling, typically starting around 6 months of age. Most babbles are of a simple and general nature (Oller, 1980), but they show language-specific effects this early as well (Boysson-Bardies *et al.*, 1984; Whalen *et al.*, 1991). Babbling continues even after the first words are mastered, and the full inventory of sounds typically takes months or even years to appear. Complex sounds are typically mastered later, including liquids (Oller, 1980) and clicks (Herbert, 1990).

Universal Patterns in Speech

Examining the sounds of the world's languages, one finds a remarkable degree of regularity. Vowels and consonants are not drawn arbitrarily from all humanly possible vocalizations. Some patterns contain sounds that are 'easy to make'; others seem to serve listener needs, presenting sound differences that are 'easy to hear' (Ladefoged, 1993).

The interaction of those forces is seen in the structure of phonetic inventories. Small systems lack segments with extreme articulations: for example, Hawaiian has /p k ʔ h m n l w/. Such series resemble the inventories of babbling and early speech. They appear 'elementary' compared with many of the consonants that are found only in very large systems. ũ, for instance, has close to 100 distinctive consonants, half of which are clicks, and nearly 50 vowels and diphthongs.

Vowels pattern similarly. A five-vowel system is likely to use /i e a o u/. Often, such a 'plain' series is matched by one or several additional systems that add an 'elaboration' in the form of a secondary articulation or a phonation type, for example, nasalization or breathy voice. It is significant that small systems recruit only elementary or plain vowels. They seldom substitute secondary for plain articulations, or show a mixture of plain, elaborated, and complex segments (Lindblom *et al.*, 1992).

How such patterns enter the language is not well understood. According to one theory, the seeds of historical sound change are sown by listener errors (Ohala, 1981). Failure to take contextual factors into account often leads to a misidentification of the intended utterance. If, when becoming the speaker, the listener adopts the misidentified form, this initiates a sound change that may spread through the speech community. In this scenario, sound change is like a mutation arising from an imperfect copying of genetic information.

There is a curious parallel between the phonetic variations of speech and the 'fossils' that they leave in phonological systems. Both seem to reflect the tug-of-war staged by the listener's need for clarity, on the one hand, and the speaker's continual propensity to simplify, on the other. Perhaps the law-governed relationships mentioned above between system size and phonetic content imply that sound systems are molded by the same factors that determine the ebb and flow of signal information in speaker–listener interactions: both must meet the criterion of 'sufficient discriminability' (Lindblom, 1990).

Because the forces that shape inventories are still active, it is difficult to determine whether they are part of a Universal Grammar (Hauser *et al.*, 2002)

or are part of a continuously tuned system. The inevitable changes in human languages indicate that there is an expected level of tension between consistent use and adaptation, to new speakers (both infant and adult) and new situations. Speech has served the needs of the 6800 or so extant language communities, and will continue to serve future generations. Like other biological systems, it is still evolving; it will be interesting to see what changes occur in its next two million years.

Spelling Reform

A Neijt, Radboud University, Nijmegen, The Netherlands

© 2006 Elsevier Ltd. All rights reserved.

The spelling of most languages changes over time. New forms such as *thru, catalog, center,* and *defense* are used alternatively for or replace the older forms *through, catalogue, centre,* and *defence*. Spelling changes are called a reform when the change is drastic, or when the spelling is institutionalized by a well-defined governmental or semigovernmental authority such as a scientific academy or a spelling board. Dictionaries and religious texts may function as authorities, but spelling changes in the form of new editions are hardly ever called spelling reforms.

From a theoretical point of view, spelling change can be considered a change of the balance between the principles on which the system is based. In alphabetic systems, the spelling serves as a solid representative of pronunciation (the phonological principle), but there are also strong tendencies to provide the meaningful elements with a consistent spelling, irrespective of variation in their pronunciation (the morphological principle that leads to paradigm similarity in writing). For instance, the ⟨t⟩ in *action* is not pronounced, but is written because of the morphological relation between *action* and *act*. In this case, the morphological principle has priority over the phonological principle. Otherwise, the spelling of *action* would be *axion* or *aksion*.

Languages naturally receive an increasingly morphological spelling over time. This can be explained in part by language change: spelling does not always follow changes in pronunciation, resulting in a new system that prefers to take morphology as its basic principle. The increasing importance of the morphological principle has also been explained by the fact that reading has priority over writing (Glück, 2000: 497). For a given text, there will be one writer, but many readers. It has been suggested that a morphological spelling system makes reading easier and faster. Speed of reading is needed because silent reading is now preferred to reading aloud. For these reasons, explicit spelling reform may cause the morphological principle to take priority over the phonological principle, even though writers and those who learn to write would prefer a spelling system based on phonology.

Spelling reform is known for its few successes and many failures. The number of proposed spelling reforms is far greater than the number of effective spelling reforms. Successful reform requires careful linguistic consideration; changing one part of the system may unintentionally affect another part of the system. It also requires psycholinguistic research into the effects of spelling change on language processing. Apart from that, diplomacy and political planning is needed because language communities tend to be conservative. Individual users will be reluctant to give up the system they learned (with much effort) and are acquainted with. Sometimes a revolutionary change of society such as the formation of a new nation helps to introduce new writing systems. It is no accident that spelling standards for languages were often formed when nations were formed.

Spelling Reform

A Neijt, Radboud University, Nijmegen, The Netherlands

© 2006 Elsevier Ltd. All rights reserved.

The spelling of most languages changes over time. New forms such as *thru, catalog, center,* and *defense* are used alternatively for or replace the older forms *through, catalogue, centre,* and *defence*. Spelling changes are called a reform when the change is drastic, or when the spelling is institutionalized by a well-defined governmental or semigovernmental authority such as a scientific academy or a spelling board. Dictionaries and religious texts may function as authorities, but spelling changes in the form of new editions are hardly ever called spelling reforms.

From a theoretical point of view, spelling change can be considered a change of the balance between the principles on which the system is based. In alphabetic systems, the spelling serves as a solid representative of pronunciation (the phonological principle), but there are also strong tendencies to provide the meaningful elements with a consistent spelling, irrespective of variation in their pronunciation (the morphological principle that leads to paradigm similarity in writing). For instance, the ⟨t⟩ in *action* is not pronounced, but is written because of the morphological relation between *action* and *act*. In this case, the morphological principle has priority over the phonological principle. Otherwise, the spelling of *action* would be *axion* or *aksion*.

Languages naturally receive an increasingly morphological spelling over time. This can be explained in part by language change: spelling does not always follow changes in pronunciation, resulting in a new system that prefers to take morphology as its basic principle. The increasing importance of the morphological principle has also been explained by the fact that reading has priority over writing (Glück, 2000: 497). For a given text, there will be one writer, but many readers. It has been suggested that a morphological spelling system makes reading easier and faster. Speed of reading is needed because silent reading is now preferred to reading aloud. For these reasons, explicit spelling reform may cause the morphological principle to take priority over the phonological principle, even though writers and those who learn to write would prefer a spelling system based on phonology.

Spelling reform is known for its few successes and many failures. The number of proposed spelling reforms is far greater than the number of effective spelling reforms. Successful reform requires careful linguistic consideration; changing one part of the system may unintentionally affect another part of the system. It also requires psycholinguistic research into the effects of spelling change on language processing. Apart from that, diplomacy and political planning is needed because language communities tend to be conservative. Individual users will be reluctant to give up the system they learned (with much effort) and are acquainted with. Sometimes a revolutionary change of society such as the formation of a new nation helps to introduce new writing systems. It is no accident that spelling standards for languages were often formed when nations were formed.

The driving forces behind a reform or a reform proposal are diverse. There may be *system-internal* motivations that concern difficulties for language users. Writers, readers, learners, or experienced users may feel that it is too hard to establish the relation between spoken and written form. To give some examples: (a) a spelling system with diacritic signs may be considered a waste of time for the writer when the written form is adequately read without such diacritics; (b) for tone languages, a spelling system without explicit marking of stress and tone may be too hard to read and understand; (c) it is hard to learn the code of alphabetic writing in a language such as English, in which the spelling of many everyday words is irregular; and (d) experienced users will develop their own system when the standard spelling does not suffice, as is the case with keyboard phonetic shorthand. When the standard spelling is incomplete or allows variants, it is usually the case that organizations create their own spelling dictionaries to reach consistency.

Such system-internal considerations may lead an authority to simplify the spelling. But whose task will become simpler? The interests of writers, readers, learners, or experienced users do not necessarily point in the same direction. A reformed spelling could simplify writing but complicate reading, or *vice versa*. It could also simplify the task of beginners but complicate the task of experienced users.

Next to system-internal motivations for reform to simplify the task of the language user, there are *external* motivations pro and contra reform. An important argument contra reform is history. Because of spelling changes, all former texts will be outmoded. It may become difficult to read texts written according to the older orthography, and cultural achievements may be lost. Literary works of art may lose value through spelling changes, because the re-spelled form may change homography and intertextual references. A new argument against reform is the help of computers; a spelling system that is difficult to write need not be changed because spell-checkers are available for corrections.

Usually, the intelligentsia is against spelling reform, cf. Fishman (1977: xvi): "Orthographic change represents the abandonment of written tradition and as such it *must* cope with the gatekeepers of written tradition, the poets, priests, principals, and professors, with the institutions and symbols they create and serve, or be destined to oblivion." Orthographic change alters the practical or symbolic advantages and disadvantages of social networks, and as such may be advantageous for one group, but not for another.

Not all external motivations are against reform. As discussed above, change of society may be the driving force of a reform because language groups or nations express their identity through their language. The wish to define a nationwide standard language usually goes hand in hand with government regulation of the spelling. Such spelling reforms concern the distance between the spelling systems for different languages or language varieties. They go both ways: they result in greater similarity between the spellings of cognate countries (for instance, to enhance commercial communication or to protect small languages), or they result in greater distance (for instance, to point up the fact that different nations or cultures are involved).

Other social motives for reform are the fight against illiteracy and the need to raise civilians who can function adequately in democracies. It is no accident that many proposals for spelling reform are put forward during the first stages of nationwide education. At present, the status of writing has been changed by the introduction of computers and the Internet. This requires higher standards of literacy and therefore also a more accessible writing system with the possibility of simplification.

There is no spelling legislation in the United Kingdom or the United States, because spelling standards are implied and need no further codification. In many other countries, a governmental or semigovernmental institution fulfills the task of formulating standard terminology and updating word lists. A spelling law prescribes which publication on spelling or which institute is in charge. The strongest form of spelling legislation is a spelling law that specifies the conventions and includes the dictionary.

Legislation of the spelling or of the installation of a government board is advantageous for language communities because a law protects language users against the preferences of single members of government (Neijt, 2002). Spelling laws provide a stable basis for a long period of time, and form the necessary basis of cooperation between countries that wish to share their written language.

Spelling laws can also be disadvantageous, however. One of the possible drawbacks of spelling regulation by law is that it puts spelling on the political agenda, whereas proposals for spelling reform need scientific underpinning; constructive discussions are more likely to occur between scholars than between politicians. Another drawback is that a law prevents the orthography from evolving naturally through small, cumulative changes. Moreover, changing an orthography via new legislation is more time-consuming and more expensive than changing it solely through

the publication of a new spelling guide. It seems that the details of spelling are better dealt with by an official publication under the auspices of a permanent spelling board than by law.

Some Examples of Spelling Regulation and Recent Reforms

Chinese: After the founding of the People's Republic of China, the government issued lists of simplified sinograms in 1956 and 1964, but Mao Zedong aimed at a more drastic reform: "we must proceed in the direction of phoneticization being taken by all languages of the world" (Seybolt and Kuei-ke Chiang, 1979). The result of this enterprise is Pinyin, the alphabetic transcription of sinograms. Whether or not Pinyin will gradually displace sinograms remains to be seen (Mair, 1996: 205). It would be one of the most far-reaching spelling reforms ever.

Danish: In 1949, there was the abolition of the capitalization of nouns and some other smaller changes.

Dutch: Cooperation between Belgium and The Netherlands has existed since the end of the 19th century considering a joint dictionary. The writing of case endings turned out to be too difficult (Geerts *et al.,* 1977). Simplification in 1934 – and its revocation in 1936 for The Netherlands – issued by successive secretaries of education. In 1947, new rules were laid down in spelling laws cooperatively in Belgium and The Netherlands. In 1954, publication of the accompanying dictionary (which was considered a further reform by the general public). In 1995, new conventions for non-native words, for linking elements in compounds and for diacritic signs (Neijt and Nunn, 1997). In 2003, Surinam accepted the new conventions as well. A new edition of the spelling dictionary with minor changes was issued in 2005. Most of the dictionary is included in the spelling laws of Flanders (the Dutch-speaking part of Belgium) and in The Netherlands.

English: No reforms, but new regional variants such as *honour/honor, apologise/apologize,* and *centre/center,* see Scragg (1974). On the one hand, changes go unnoticed, but on the other, language users are not allowed to use the 'wrong' spelling. In the words of Cook (2004: 178): "A paper of mine was returned with the comment 'American spelling for an American journal': no one has ever required me to use an American accent for an American conference."

French: The Académie Française is the authority on spelling issues. The orthography is also regulated by terminology lists and dictionaries edited by governmental institutions (Institut National de la langue française and Centre de terminologie et de néologie). In 1990, the spelling board of the Académie Française (the Conseil supérieur de la langue française) published a simplified spelling list with variants: optional use of circumflexes in some words (e.g., *août* or *aout* 'August' and *dîner* or *diner* 'dinner'), and ligatures such as ⟨æ⟩ may be written as ⟨é⟩. These variants were not accepted by *Petit Robert*, the standard dictionary in France. The older spelling is still the only one used in the dictionary of the academy (1st edn., 1694, see Academie Francaise). The spelling of Quebec French is regulated in a similar way. A law in 1977 installed the Office de la langue française, which handles terminology (see Banque Terminologique du Quebec).

German: Since 1876, there has been cooperation among the German-speaking countries, with a 'compromise spelling regulation' in 1901 and script reform in 1941. Latin script displaced the German scripts (Gothic, Schwabacher and Fraktur), which were illegible for readers outside the German states (Augst, 1996: 77). A reform was decided upon in 1996 (transitional period until 2005). This reform encountered difficulties because of the intricate political organization (cooperation among Germany, Austria, and Switzerland, but with authoritative Bundesministers in the federal states of Germany) and the linguistic dispute (cf. compromise proposal *Zur Reform der deutschen Rechtschreibung* by the Deutschen Akademie für Sprache und Dichtung, 2002). The main issues are the use of Eszett ⟨ß⟩, spaces in compound verbs (*autofahren* or *Auto fahren* 'to drive a car'), vowels (according to the morphological principle, e.g., *Stängel* 'stick' because of *Stange* 'rod,' or according to the phonological principle *Stengel*), and capital letters in phrases such as *das folgende* or *das Folgende* 'the next' and *im bezug auf* or *im Bezug auf* 'with respect to.'

Japanese: In 1949, the government installed a national spelling board, the Kokugo Singikai. In 1981, this board published a reduced list of characters in which older variants of kanji and kana are dropped.

Lithuanian: At the end of the 19th century, the use of *č* and *š* in prestige books formed the incentive for the American Lithuanian community to use these letters instead of the traditional digraphs *sz* and *cz,* in journals, too (Subačius, 2004).

Norwegian: The original Danish spelling of the main written language, Bokmål, was not adequately understood and used (Gundersen, 1977: 250). Reforms in 1907 (abandoning capitalization of nouns), 1917, 1938, 1959, and 1981 by Royal Decrees (smaller changes). The government is advised by the Norsk Språkråd.

Russia and the Balkans: See Comrie (1996) for an overview. Baldauf (1993) presents extensive

documentation of spelling changes in Russian Turkophone languages between 1850 and 1937 (Azerbaijani Turkish, Bashkir, Karakalpak, Kazakh, Kyrgyz, Crimean Tatar, Tatar, Turkmen, Uighur, and Uzbek). She discusses the link between spelling reform on the one hand, and modernization and the creation of nations on the other.

Spanish: Cooperation between countries via the Real Academia Española in Madrid, which has published new principles and guidelines in *Ortografia de la lengua española* (1999). The spelling dictionary includes only words with a Spanish pronunciation, such that the orthography is almost completely regular. In 1910 and 1955, there was the abolition of several diacritic signs, but there is still debate on how to establish a simpler set of rules. The writer Gabriel García Márquez also pleads for simpler rules for the letters *h, g,* or *j*, and *b* or *v* (Marquez).

Tone languages: Illustrative are Shilluk and Dinka (Nilo-Saharan languages). The orthographies developed by non-native speakers in the early and mid-20th century are inadequate for the needs of native speakers. While the languages are easy to write, they are almost impossible to read fluently because tone and stress, which contribute to the meaning of words and word groups, are not represented. Recently, new orthographies have been developed that make reading easier. Writing, however, is more difficult in the revised spelling (Gilley, 2004).

Turkish: Major spelling reform with a change from Arabic script to Roman script occurred in 1928, after the foundation of the Republic of Turkey in 1923.

function: *debt*, *know*, *psalm*, *mnemonic*, *island*, *victuals*. The same vowel sound may be represented by different letters: in the phrase *pretty village women*, for example, all six vowel letters represent the same sound (in many accents at least). The same letter, on the other hand, may represent different sounds, as ⟨a⟩ does in *father washed the cabbage in a basin of salt water*. Removal of these anomalies, spelling reformers claimed, would bring benefits of many kinds. For one thing, Truth would at last prevail, the present orthography being "one great falsehood from beginning to end," as one reformer put it. For another, money would be saved by economizing writing and printing time and space. Above all, it would simplify learning to read and write; and incidentally make learning English easier for foreigners.

Types of Reform

It was not until the 19th century that there arose in the United Kingdom and the United States spelling reform **movements,** with funds and an organization; but many suggestions for reform were put forward during the three centuries before that. The suggestions variously involved either staying with, or augmenting, or replacing, the roman alphabet. They are listed in Brown (1991).

English orthography can be made less odd by an **amended** spelling, with most of the illogicalities and inconsistencies eliminated. This does not, however, solve the difficulty that the number of sounds that have to be distinguished in English is greater than the number of letters in the alphabet. One solution for this is to retain the roman alphabet but to add to the number of digraphs, such as ⟨th⟩, ⟨sh⟩, ⟨ng⟩, ⟨ee⟩, that already exist. Or the alphabet may be augmented by new letters. Or – most radical solution of all – the roman alphabet may be abandoned altogether and replaced by a new, nonroman alphabet.

Amended Spelling

James Howell is perhaps the best-known advocate of an amended spelling. In *A new English grammar* (1662), he put forward a number of simplifying rules; thus, he suggests *som*, *don* (for *some*, *done*), *peeple*, *toung*, *favor*, *tresure*. Familiar to generations of librarians is the scheme of the (USA) 'Simplifyd Speling Board,' which was used in each edition of the Decimal Classification devised by Melvil Dewey (1851–1931) through the 14th (1942).

Another example is 'cut spelling,' one of the schemes advocated by members of the (UK) Simplified Spelling Society. Cut spelling omits many redundant or unnecessary letters, as in the word *spelng* itself, but the general appearance of the traditional word-outline is preserved. Other examples are *larjst*, *finishd*, *problm*, *irelevnt*. A full account is given in Upward (1992).

Digraphic Spelling

James Elphinston, in *Propriety ascertained in her picture* (1787) and a number of other works, proposed a digraphic scheme, which aroused great scorn and ridicule among his contemporaries. Nevertheless the Simplified Spelling Society has adopted the digraphic solution, which is the least demanding of the printer, for its other scheme, 'new spelling' (see MacCarthy, 1964; Ripman and Archer, 1948).

Augmented Roman Spelling

By far the greatest number of schemes come into this category, from the 16th to the 20th century. Notable advocates are Sir Thomas Smith, John Hart, Alexander Gill, Benjamin Franklin, Abner Kneeland, Isaac Pitman, A. J. Ellis, and Ezekiel Rich. New letters were obtained by borrowing from Greek (⟨ε⟩ ⟨η⟩ ⟨χ⟩ ⟨ω⟩) or Anglo-Saxon (⟨ð⟩ ⟨þ⟩), by modifying existing letters (⟨ŋ⟩ ⟨ʒ⟩), and by outright invention (⟨□⟩).

A New Alphabet

The best-known example of a nonroman orthography for English is the Shaw Alphabet, the creation of which was made possible by a bequest made by George Bernard Shaw in his will when he died in 1950. He believed that the imposition of Received Pronunciation (RP) via surface-phonetic orthography would force the lower classes to abandon their inferior dialects (1941; so much for the vaunted Shavian socialism!). A competition was held for the design of a new alphabet. The design submitted by Kingsley Read was selected as the basis of the new alphabet, and a play of Shaw's was published in 1962 with the text in traditional spelling and in the new alphabet on facing pages (see Figure 1).

An experiment in pedagogy, the Initial Teaching Alphabet (ita) of Sir James Pitman (Figure 2), was supposed to ease children into reading English because the shapes of the characters resembled the usual digraphs of 'traditional orthography' (TO). It received some currency in the United Kingdom and slight usage in the United States in the 1960s. Its advocates (e.g., Downing, 1965 for parents; Pitman and St. John, 1969 for researchers) demonstrated the efficacy of ita in accelerating mastery of reading, including the transition to reading TO, but barely addressed, let alone assessed, the transition to **writing** TO (Pitman and St. John, 1969: 180–181); anecdote indicates that people raised on ita do not master standard spelling.

Figure 1 The Shaw Alphabet for Writers. Double lines between pairs show the relative height of talls, deeps, and shorts. Wherever possible, finish letters rightwards; those starred will be written upwards.

The Desirability of Spelling Reform

It may well be that the oddness of English orthography is only superficial, and that the supposed need for reform is based on a misconception. It may be that "English orthography comes remarkably close to being an optimal orthographic system for English" (Chomsky and Halle, 1968). If it is assumed that the function of writing is to represent the sounds of speech in the same way as the sound of music is represented by its notation, then English spelling is gravely deficient and in need of reform. But, while the representation of sound is the end in itself in musical notation, for writing it is only the means to an end, the end being the creation of a visual medium for carrying language. Several analyses of spelling-to-sound correspondences have been published: Wijk (1966), in effect a prolegomenon to the author's spelling reform proposal (Wijk, 1977); Venezky (1970); and Carney (1994). Sound-to-spelling correspondences are detailed by Carney and in Cummings (1988), the former for British, the latter for American orthography.

A fallacy underlying the concept of reform, thus, is the assumption that an ideal orthography reflects the surface phonetics of its language. But if every variety

Figure 2 The Initial Teaching Alphabet (Pitman and St. John, 1969: 119).

of English were recorded according to its own pronunciation, communication among users of disparate varieties would be impaired; and even if the pronunciation of a standard variety – e.g., RP (as advocated by Shaw), or General American – were chosen for the orthographic standard, then the visual relation of *sign/signature*, *bomb/bombard* would be eliminated.

On a perhaps more frivolous level, reform would remove the possibility of joke spellings like *ghoti* for *fish*, with ⟨gh⟩ as in *rough*, ⟨o⟩ as in *women*, and ⟨ti⟩ as in *nation*; or the spelling of the *cacophony* which often comes from the audience at the beginning of a concert as *cacoughany*.

It could be that it is not so much English spelling that needs reforming as our attitude towards spelling. The 19th-century idea of 'correct' spelling is nowadays accepted without question. A representative of the Simplified Spelling Society has stated that "one of the most important things about writing systems is that people should learn to write a language in an accepted way." On the other hand, a Member of Parliament has said, in the House of Commons, "I want to restore flexibility and liberty to the spelling of our own language. I want to set English free again from the shackles of uniformity which have been imposed upon it." If this could be brought about, it is possible that English orthography would evolve, without legislation or propaganda, into a linguistically optimum form. What has been seen in recent years, though, as a new generation at home with instantaneous international written communication strives for speed in typing above all, is the emergence of a 'keyboard phonetic shorthand' embracing logograms and character names rather than strictly phonetic orthography: *Ill b there @ 4, UB2!* (Cook 2004: 193–203).

Spence, Thomas (1750–1814)

M Garcarz, Uniwersytet Wroclawski, Wroclaw, Poland

© 2006 Elsevier Ltd. All rights reserved.

Thomas Spence, an English social philosopher and humanist, was born on June 21, 1750 on the Quayside, Newcastle upon Tyne. His father was a simple net maker, and Thomas was one his 19 children. It has never been clearly stated what school Spence attended, because at the age of 10 he decided to help his father in net making. Influenced by his parents, who were radical Presbyterians, Spence started studying the Old Testament. The egalitarian ideas promoted by the Old Testament influenced Spence and shaped his moral values. He could not understand the unresolved contrast between the idea of equality of men conceived by God and the differences that people saw between a sovereign and a common man. Spence opened a school in which he organized a debating club that became a secular pulpit for the spread of his revolutionary ideas. Spence strongly believed in land reforms; he claimed that every parish ought to become a fully autonomic social unit, and that all lands should be nationalized.

Spence perfectly understood that in order to become a credible and trustworthy person, he needed to erase his northern dialect. Spence invented a phonetic alphabet to improve his pronunciation which, later modified, gave the basis for the standard form of English. In Spence's view, the unification of the spelling system was strictly linked with the reform of the political system in a state: one society should use one language. A number of his books were written with the application of his spelling reforms (*The grand repository of the English language* was published in 1775).

One might call him the first British advocate of the equality of social classes, a true proponent of the class war communism. In 1774, Spence became a member of the Newcastle Philosophical Society. One year later, on November 8, 1775, he gave a memorable revolutionary speech entitled *On the mode of administering the landed estate of the nation as a joint stock property in parochial partnership by dividing the rent*. In consequence, Spence was permanently expelled from the society. Then he moved to London, where in 1793 he opened 'The hive of liberty,' a shop where he promoted radical books and pamphlets. In 1794, Spence launched a periodical, *Pig's Meat*, which was suspended; Spence himself was arrested and charged with treason. He spent seven months in prison. Later, he opened a shop again, but this time with soft drinks and tokens.

Spence was a visionary of social reforms in England in his time. He acted against tyrants and strongly advocated women's rights, because he believed that people were righteous, virtuous, and therefore equal. Thomas Spence died on September 1, 1814, at the age of 64.

Spitzer, Leo (1887–1960)

D Candel, CNRS and Université Paris 7, Paris, France

© 2006 Elsevier Ltd. All rights reserved.

Spitzer was born in Vienna. A student of Meyer-Lübke, he was also influenced by Schuchardt and Freud. He became a professor in Bonn (1922), Marburg (1925) and Cologne (1930), and in 1933 was forced to flee from Nazi Germany to Istanbul and then in 1936 to Baltimore (Johns Hopkins University). Defending individual creativity in his studies of historical semantics, Spitzer distanced himself from an individualistic conception of language (the likes of Schuchardt, Vossler, and Croce). Strongly against positivism, and in opposition to both idealistic linguistics and reductionist scientific linguistics, he reached a synthesis between linguistics and critical literature. Proposing a stylistics founded on

interpretation and intuition, he placed authors' specificity above language facts (Bally), and considered that deviations from the norm in writers' style denoted a historical step.

Spitzer studied individual linguistic styles ('*Sprachstyle*') as well as transverse stylistic languages ('*langues stylistiques*'). Linguistic and philological information served interpretative purposes, in order to 'bridge the gap between linguistics and literary history.' The stylistician first placed himself in the middle of the text and observed it deeply (the inductive phase), and then went through a methodic analysis of a number of parts of the text, in search of indices allowing him to check the starting hypothesis (the deductive phase). This psychological and formal method of the 'inductive–deductive circle' is a constant back-and-forth movement between effective expression and inspiring act.

Spitzer is known as the leader of literary stylistics. He strongly contributed to turning stylistics into a discipline. Spitzer was criticized by Bruneau, who was essentially looking for quantitative data, and Riffaterre, who denied, in structural stylistics, the importance given to the writer. In the United States, supporters of the 'New Criticism' did not agree with Spitzer. He referred to his work as *Stilforschung* (cultural interpretation of style-philology) and as *Stilistik* (Bally's '*stylistique*'). He wanted to offset the risk, in 'general scientific linguistics,' of an increasingly positivistic tone dominating a less formal sociocultural interpretation. This tension remains at the heart of modern stylistics. Spitzer developed the grammaticalization of stylistics, foretelling Marouzeau and Cressot. His methodology became a commonplace one in literary stylistics and text linguistics.

Splinters

L Bauer, Victoria University of Wellington, Wellington, New Zealand

© 2006 Elsevier Ltd. All rights reserved.

A splinter is a part of a word that, due to some reanalysis of the structure of the original word, is interpreted as meaningful, and is then subsequently used in the creation of new words. As a familiar example, consider the word *alcoholic*. In morphological terms, this is divided into *alcohol* and *-ic*. But this word has been reanalyzed as *alc-* and *-oholic*, and the new splinter *-oholic* (variously spelled) then reoccurs in words such as *chocoholic, spendaholic,* and *shopoholic*.

Splinters are sometimes reanalyzed as words, sometimes as affixes, and sometimes as word-building elements that do not appear to have any particular denotation. For example, *hamburger* was reanalyzed from its original structure of *Hamburg-er* ('of or originating in the city of Hamburg') to *ham-burger*, and *burger* is perceived as a new word (accordingly, *cheese-burger* is perceived as a compound). The *-(n)omics* that we find in *Reaganomics, Clintonomics, Thatchernomics,* etc., appears to have been reanalyzed as an affix or as a combining form (*see* **Neoclassical Compounding**). The *-on* that we find in *dralon, nylon, rayon, xenon* and so on does not carry any denotation, but does contain a connotation of scientific progress, while the final *-x* that occurs in trade names such as *Clorox, Cutex, Kleenex, Pyrex,* and *Tampax* does not appear to have a meaning at all, but seems to mark these words as trade names (see Thornton, 2000). Which of these analyses is perceived

interpretation and intuition, he placed authors' specificity above language facts (Bally), and considered that deviations from the norm in writers' style denoted a historical step.

Spitzer studied individual linguistic styles ('*Sprachstyle*') as well as transverse stylistic languages ('*langues stylistiques*'). Linguistic and philological information served interpretative purposes, in order to 'bridge the gap between linguistics and literary history.' The stylistician first placed himself in the middle of the text and observed it deeply (the inductive phase), and then went through a methodic analysis of a number of parts of the text, in search of indices allowing him to check the starting hypothesis (the deductive phase). This psychological and formal method of the 'inductive–deductive circle' is a constant back-and-forth movement between effective expression and inspiring act.

Spitzer is known as the leader of literary stylistics. He strongly contributed to turning stylistics into a discipline. Spitzer was criticized by Bruneau, who was essentially looking for quantitative data, and Riffaterre, who denied, in structural stylistics, the importance given to the writer. In the United States, supporters of the 'New Criticism' did not agree with Spitzer. He referred to his work as *Stilforschung* (cultural interpretation of style-philology) and as *Stilistik* (Bally's '*stylistique*'). He wanted to offset the risk, in 'general scientific linguistics,' of an increasingly positivistic tone dominating a less formal sociocultural interpretation. This tension remains at the heart of modern stylistics. Spitzer developed the grammaticalization of stylistics, foretelling Marouzeau and Cressot. His methodology became a commonplace one in literary stylistics and text linguistics.

Splinters

L Bauer, Victoria University of Wellington, Wellington, New Zealand

© 2006 Elsevier Ltd. All rights reserved.

A splinter is a part of a word that, due to some reanalysis of the structure of the original word, is interpreted as meaningful, and is then subsequently used in the creation of new words. As a familiar example, consider the word *alcoholic*. In morphological terms, this is divided into *alcohol* and *-ic*. But this word has been reanalyzed as *alc-* and *-oholic*, and the new splinter *-oholic* (variously spelled) then reoccurs in words such as *chocoholic, spendaholic,* and *shopoholic*.

Splinters are sometimes reanalyzed as words, sometimes as affixes, and sometimes as word-building elements that do not appear to have any particular denotation. For example, *hamburger* was reanalyzed from its original structure of *Hamburg-er* ('of or originating in the city of Hamburg') to *ham-burger*, and *burger* is perceived as a new word (accordingly, *cheese-burger* is perceived as a compound). The *-(n)omics* that we find in *Reaganomics, Clintonomics, Thatchernomics,* etc., appears to have been reanalyzed as an affix or as a combining form (*see* **Neoclassical Compounding**). The *-on* that we find in *dralon, nylon, rayon, xenon* and so on does not carry any denotation, but does contain a connotation of scientific progress, while the final *-x* that occurs in trade names such as *Clorox, Cutex, Kleenex, Pyrex,* and *Tampax* does not appear to have a meaning at all, but seems to mark these words as trade names (see Thornton, 2000). Which of these analyses is perceived

seems to be determined by the paradigms in which the new words are found.

According to Adams (1973: 147), the term 'splinter' comes from Berman (1961). Adams uses the term specifically to refer to those parts of a blend (*see* **Blend**) that are descended from each of the input words to the blend, though the sources of splinters as given here may be rather wider than that.

Spoken Discourse: Diachronic Aspects

A Narbona Jimènez, Universidad de Sevilla, Sevilla, Spain

© 2006 Elsevier Ltd. All rights reserved.

The written word, in those languages in which it has been established, did not emerge as a means of reflecting spoken language, which is the most powerful generator of constant and inevitable linguistic innovation, alteration, and loss (only **dead** languages do not change) and whose development has been relatively autonomous. However, paradoxically for the language historian, it is possible to discover these changes only through written testaments – always few in number and never absolutely reliable.

This did not go unnoticed by the father of modern linguistics, F. de Saussure, who, in the introduction to his well-known *Cours de linguistique générale* (1985), though he maintained that the spoken and the written were two systems with distinct signs ("*langue et écriture sont deux systèmes de signes distincts*") and that the latter was in itself foreign to the internal system ("*en elle-même étrangère au système interne*"), recognized that we generally know the spoken only via the written ("*nous ne les* [*les langues*] *connaissons généralement que par l'écriture*").

It was only once the technical means became available to record oral speech acts, as well as the situations and contexts in which they take place, that it became possible for the linguist to examine the particular conditions of their production and reception, their contextualizing procedures, and thus their specific organization.

The question of data is thus decisive, and not only for the language historian. As Mary-Annick Morel and Laurent Danon-Boileau state in their book entitled *Grammaire de l'intonation* (1998), there is a world of difference between spoken and written language and the difference is so great that the description of spoken French is often closer to that of an exotic language than to written French ("*De l'oral à l'écrit il y a un monde. La différence est si grande que la description du français oral ressemble plus souvent à celle d'une langue exotique qu'à celle du français écrit*").

This being so, consider the difficulties in trying to understand the oral manifestations of the past based only on clues found within those written sources that have reached us.

It would of course be wrong, however, to suppose that linguistic acts that take place via the phonic–auditory channel and the graphic (visual) media have nothing in common. The reciprocal interrelationships, always dynamic and changing, between **all** varieties of use are becoming increasingly close and intense, and the permeability between oral and written language is particularly marked. Political, economic, and sociocultural factors (the processes of national unity, administrative centralization, increased speaker mobility, industrialization, schooling and literacy, the role of the media, etc.) have enabled new strata of the population to become part of the written culture and to participate in the process of standardization of what we call written language.

We should not simplistically separate spoken language (spoken English, *français parlé*, *italiano parlato*, *español hablado* . . .) from written language, but rather all modalities should be contemplated within one gradual and multiparametrical scale in which, ultimately, the level of accommodation and complicity (or divergence) that exists between those who take part in a given speech act and the register or the discourse tradition will determine the choices made in each case.

The need to revise the history of language from a variationist perspective is, in part, the consequence of

seems to be determined by the paradigms in which the new words are found.

Spoken Discourse: Diachronic Aspects

A Narbona Jimènez, Universidad de Sevilla, Sevilla, Spain

© 2006 Elsevier Ltd. All rights reserved.

The written word, in those languages in which it has been established, did not emerge as a means of reflecting spoken language, which is the most powerful generator of constant and inevitable linguistic innovation, alteration, and loss (only **dead** languages do not change) and whose development has been relatively autonomous. However, paradoxically for the language historian, it is possible to discover these changes only through written testaments – always few in number and never absolutely reliable.

This did not go unnoticed by the father of modern linguistics, F. de Saussure, who, in the introduction to his well-known *Cours de linguistique générale* (1985), though he maintained that the spoken and the written were two systems with distinct signs ("*langue et écriture sont deux systèmes de signes distincts*") and that the latter was in itself foreign to the internal system ("*en elle-même étrangère au système interne*"), recognized that we generally know the spoken only via the written ("*nous ne les* [*les langues*] *connaissons généralement que par l'écriture*").

It was only once the technical means became available to record oral speech acts, as well as the situations and contexts in which they take place, that it became possible for the linguist to examine the particular conditions of their production and reception, their contextualizing procedures, and thus their specific organization.

The question of data is thus decisive, and not only for the language historian. As Mary-Annick Morel and Laurent Danon-Boileau state in their book entitled *Grammaire de l'intonation* (1998), there is a world of difference between spoken and written language and the difference is so great that the description of spoken French is often closer to that of an exotic language than to written French ("*De l'oral à l'écrit il y a un monde. La différence est si grande que la description du français oral ressemble plus souvent à celle d'une langue exotique qu'à celle du français écrit*").

This being so, consider the difficulties in trying to understand the oral manifestations of the past based only on clues found within those written sources that have reached us.

It would of course be wrong, however, to suppose that linguistic acts that take place via the phonic–auditory channel and the graphic (visual) media have nothing in common. The reciprocal interrelationships, always dynamic and changing, between **all** varieties of use are becoming increasingly close and intense, and the permeability between oral and written language is particularly marked. Political, economic, and sociocultural factors (the processes of national unity, administrative centralization, increased speaker mobility, industrialization, schooling and literacy, the role of the media, etc.) have enabled new strata of the population to become part of the written culture and to participate in the process of standardization of what we call written language.

We should not simplistically separate spoken language (spoken English, *français parlé*, *italiano parlato*, *español hablado* . . .) from written language, but rather all modalities should be contemplated within one gradual and multiparametrical scale in which, ultimately, the level of accommodation and complicity (or divergence) that exists between those who take part in a given speech act and the register or the discourse tradition will determine the choices made in each case.

The need to revise the history of language from a variationist perspective is, in part, the consequence of

the search for traces or vestiges of oral language in the past. It has become necessary, not only to widen the range of the sources that, until relatively recently, have shown a preference for literary texts, but also to effectively consider the reciprocal interrelations that at each stage have existed between the written and the spoken. However, although levels of literacy vary from region to region, we should not lose sight of the fact that those populations able to read and write have been few and far between. Nor should we forget that the researcher studying the early development of written language is almost always groping in the dark, thereby giving rise, for example, to a considerable diversity of opinions of what was spoken in each area of Romania between the 8th and 11th centuries and to what extent it had diverged from written Latin. Nevertheless, it seems clear that advances are unlikely to be spectacular in those areas that would appear to be most relevant in helping us reach a conceptual understanding of oral language, that is, those constructive techniques used in situations of communicative immediacy or proximity. It is not possible to write as we speak (nor, of course, do we speak as we write), no matter how often this desire for such a stylistic ideal may be expressed.

The approximate reconstruction of the phonological system and its changes has been achieved relatively successfully, especially in those languages where texts exist to guarantee continuity and where comparisons can be made with other closely related languages. It is also possible to deduce the differences in accent preferences, when comparing, for example, Italian items such as *popolo* o *tavolo* with the corresponding terms in French (*peuble, table*) or Spanish (*pueblo, tabla*).

The same can be said of the history of lexicon, although the explanation of changes in meaning is somewhat more complex than that of phonetic alteration, involving a simultaneous examination of internal and external causes. At times this task is not excessively problematic. The fact that a derivative of the Germanic *blank* was implemented in most of the Romance languages (fr. *blanc,* it. *bianco,* esp. *blanco*) at the expense of the Latin *candidus*, and that *albus* was preserved only in learned environments, provides semantic evidence, albeit indirect. Similarly, derivatives of *domus* were not adopted as new conceptualizations of *abodes* or *dwellings* emerged, although it is necessary to explain why some opted for *casa* and others for *mansione*.

In most cases, however, the task is an arduous one. It is not easy to establish the limits between a linguistic textual analysis and a critical philological interpretation. Furthermore, it is necessary to have an adequate knowledge of the pragmatic implications of the expressions found in the texts, be they literary or nonliterary. In order to unravel the meaning of one single word, *auze* ('luck', 'fortune'), which disappeared from Castilian texts at the end of the Middle Ages, F. de Bustos Tovar (2000) found it necessary to consider simultaneously the problems of etymology, morphology, discourse analysis, etc. Furthermore, in order to understand something of the mysterious and random future of humans, one cannot forget that the observation of the flight and movement of birds led to the predictions of astrologers based on careful contemplation of the stars. The same author (de Bustos Tovar, in press) adopted a similar approach with the term *mantenencia* ('sustenance', 'support'), derived from *mantener* and common to all Western Romance languages. In all cases, however, it is almost always difficult to ascertain to what extent this is to do with the real vitality of the expressions since this requires data that are not normally found in written texts. Linguistic meaning is permanently subject to two types of tension: between stability and instability, on the one hand, and between what is denoted and the sense it truly offers, on the other hand. All this serves to emphasize the grades and contours or hazy boundaries of meaning.

With the particular discourse syntax of spoken language, however, we must be content with the formulation of plausible hypotheses. Years of research into the particular constructive strategies of *français parlé* have led Claire-Blanche Benveniste and her group to suggest that its syntax is characterized by the special type of organization and planning it implies. In particular, conversational language allows us to see numerous traces and vestiges of the stages of the process of the production of utterances, that is, the successive choices the speaker is faced with before reaching the final product. The paradigmatic accumulation, the continuous stoppings, startings, and detours that take place in the confection of the sequences, and the frequent additions and fillers create a very different climate than that found in written language. All this ultimately has to do with the fact that the oral varieties, particularly the prototypically colloquial ones, are strongly rooted to the conditions needed in a communicative situation in which the exploitation of determinant resources (e.g., prosodic) is decisive for the acquisition of meaning.

Little of this can be retrieved from the writings of the past. One should not, of course, dismiss the possibility of reviving and actualizing the written word. In this way, Alonso (1925) managed to explain the actual meaning of *como que y cómo que*, common expressions (*-¿Cómo que no lo sabías?-¡Como que no lo sabía* ('How come you didn't know? Because I didn't!')) that were already present in medieval

texts. This, however, in no way implies that the past should, nor can, be explained from the reality of the present.

One cannot be careful enough to avoid the hierarchical deformation that often influences explanations. It should be remembered that syntactic variables that are never, or hardly ever, found in the writing of the past should not be considered variants of those that, precisely since they do, are thought of as invariants and, more often than not, **superior**. The difficulty in projecting the principle that Rosanna Sornicola (2002) referred to as the *relatività della variazione* (the possibility of a variationist linguistic approach without reference to homogeneity as a **logically** preceding concept) does not mean that it should be ignored. Whether the dominant Romance word order in basic predicative structures has or has not become S(ubject)–V(erb)–O(bject) and discussions about the preferred argument structures of each language should not be posed in general terms once and for all, but rather should be seen in each case in terms of the particular register, discourse tradition, and communicative situation. Failure to adopt this type of caution leads, for example, to sequences such as *el periódico ¿lo compras tú?* ('Is it you who is going to buy the newspaper? Are you going to buy the newspaper?') being qualified as *dislocated* ('to the left') when they are standard and commonly used in spoken language and with a pragmatic efficiency that cannot be matched by more syntactically controlled forms (*¿compras (tú) el periódico*?). Similarly, without circumspection *allí es donde deberíamos haber ido* ('That is where we should have gone') would be simply interpreted as a split construction 'derived' from *deberíamos haber ido allí* ('We should have gone there') or *que* might be considered as a **weak** relative in common usages (also, incidentally, dating back to the origins of Romance languages) such as *es una mujer que lo primero que destaca en ella es su elegancia* ('The first thing that strikes one about that woman is her beauty').

In general terms, the historical study of spoken language should abandon the prejudiced point of view that considers the maturing process of languages as lineal and unique, a belief that is based precisely on the exclusive or preferential observation of the facts as presented through written texts. The widely held belief that the use of mechanisms of **subordination** has been increasing with time at the expense of **paratactic** resources does not apply uniformly to all types of language. The integration and structuring of utterances (sentential or not) in oral discourse are achieved through various means, some of which have little to do with those described by grammarians whose knowledge is markedly philological.

More may be deduced about the spoken language of the past as the traditional sentential approach to the study of syntax continues to give way to a pragmatic approach. However, despite these advances, including the incipient configuration of historical dialectology and sociolinguistics, there is something that will always remain fundamentally out of reach of language historians: the divergences derived from the different levels of linguistic and communicative competence reached by the given speakers. The varying capacities of individuals to make use, both actively and passively, of the various oral registers (particularly because until fairly recently the written word was available to very few) cannot be gleaned through the written word. In this sense, F. de Saussure is accurate in his observation that writing veils and disguises the spoken language rather than dresses it: "*l'écriture voile la vue de la langue: elle n'est pas un vêtement, mais un travestissement*."

Spoken Discourse: Morphophonological Aspects

P Como, Università di Napoli, Napoli, Italy

© 2006 Elsevier Ltd. All rights reserved.

Introduction

Morphophonology is one of the most complex technical terms used in linguistics. There are debates surrounding not only the terminology ('morphophonology,' 'morphonology,' and 'morphophonemics' are not exact synonyms), but also its specific subject matter, the subject's boundaries, and its status within the general framework of linguistic theory (for a historical survey of the notion, see Kilbury, 1976).

A broad, if not unproblematic, definition of morphophonology includes the study of the phonological shape and structure of morphemes, of morpheme-boundaries and of alternations that have a morphological function in a language (Trubetzkoy, 1929). A certain kind of alternation is recoverable, for instance, in the English verbal opposition *give*~*gave*, in which vocalic quality (ablaut) distinguishes between the tenses. An alternation can remain productive (e.g., substandard *bring*~*brang)*, and in some cases it can coexist with a concomitant marker of the morphological distinction alongside the primary [marker like, for instance, the German singular/plural pair hand~hände 'hand(s)' in which the plurality is additionally marked by the suffix -e] (Van Coetsem and McCormick, 1990).

A great number of studies have taken morphophonological phenomena into account from different perspectives and with differing levels of detail, depending on theoretical complexity, itself closely tied to important changes in practice in phonology and morphology over the last thirty years (see, among others, Dressler, 1985; Maiden, 1991; Singh, 1994; Ito and Mester, 2003). However, very little research has been done on spoken discourse and, more specifically, on utterances produced during actual interactions between people. In fact, previous theories and sets of rules that were proposed in the literature in order to explain alternations are based partly on investigation of written corpora, partly on introspection, and partly on material elicited *ad hoc*, using linguistic questionnaires or laboratory techniques.

As will be illustrated in the following sections, the analysis of how morphophonological alternations function in discourse can actually be very illuminating: it helps in testing the validity of the various theoretical approaches in morphophonology; it facilitates verifying some assumptions about how the speaker interprets the alternations; and it provides us with evidence about the way these phenomena function during actual interactions.

Early Approaches to Morphophonology: Abstraction from Discourse

It is no accident that the two seminal articles of the American morphophonemics school were written by two field-oriented descriptivists interested in Native American languages: Bloomfield (1939) and Voegelin (1935), working on Menomini and Tübatulabal morphophonemics respectively. Since Bloomfield's work, however, researchers in morphophonemics have become mainly interested in the distributional analysis of series of alternations, in order to discover and then formulate rules for the transformation of phonological sequences into morphological ones. Sometimes the succinctness of elegant theoretical approaches not only has obscured the actual speakers behind the language but has led to the use of excessively abstract input and a theoretical apparatus that is too complex. Hockett, at the end of the 1960s, complained about the fact that almost all theorists considered morphophonemes to be true linguistic elements rather than merely a construct existing at a certain level of abstraction as a tool useful for linguistic description and analysis: "If the search for economical morphophonemic notations and rules is going to lead us into this trap in the future as it has in the last couple of decades the price paid for the resulting succinctness of statements is too high" (Hockett, 1967: 221). Even recently, the majority of studies situate morphophonological alternations in spoken language within specific theoretical models at some degree of abstraction, in order to prove the explanatory power of a particular paradigm, or to provide data about how language works (see, for instance, Alderete, 2001; Trón and Rebrus, 2001; Vajda, 2001).

Morphophonology and the Speaker

It is still a matter of debate whether morphophonological rules play a role in speech processing and speech production. Bottom-up (using only acoustic information to decode the speech signal) and top-down processes (the use of semantic and morphosyntactic information) appear to operate together in word identification in conversational speech (Ernestus *et al.*, 2002). It has been demonstrated through experimental research on sound perception and language processing that people tend to hear what they 'should hear' in relation to their knowledge of language, together with the contextual situation and orthography,

Table 1 Metaphonic raising

High mid	/e/	→	/i/				
	/o/	→	/u/				
Low mid	/ɛ/	→	/jɛ/	or	/je/	or	/e/
	/ɔ/	→	/wɔ/	or	/wo/	or	/o/
	/a/	→	/ɛ/	or	/je/		

rather than merely hearing the physical sounds of the speech signal. An experiment on French, for instance, demonstrates that in combinations of morphemes in words like 'absurd,' morphologically analyzable as {ab-}+{surd}, and phonetically as [apsyrd], the realization of /b/ before the unvoiced consonant, as a labial stop, is perceived as [p], but it is analyzed by the speaker as a voiced consonant. In the authors' opinion (Hallé *et al.*, 2000) there are two possible interpretations of the data. The first relies on cohort activation, consistent with the graphic code: the code /b/ is lexically mediated by a cohort of words that are phonetically compatible with the acoustic input spelled with a 'b.' The second hypothesis is based on prefix activation, by means of a morphophonemic code. This second explanation is not as well supported by findings reported in other studies, and, in any case, the role of morphonological code in word recognition is still a matter of debate.

As regards speech production, on the other hand, some studies conducted within the 'slips of the tongue' and 'errors in speech' frameworks (Fromkin, 1971: 40–42) and others on language deficit and language impairment (Macoir and Béland, 1998) support the relevance of morphophonological constraints and segmental units during actual speech production (for more information on morphophonological word encoding in speech production, see Levelt *et al.*, 1999). Thus, it appears that the morphophonological level is at the very least a useful tool for describing some types of performance error and some language impairments.

Evidence from Discourse

The analysis of morphophonological phenomena in spoken discourse can sometimes throw up intriguing anomalies as regards the way language works and consequently prompts new questions about the theoretical accounts. A specific example will be useful here. In a well-documented monograph on morphonology, Maiden (1991) considers metaphonetic alternation in Southern Italian dialects. Metaphony is a type of assimilatory phenomenon, akin to Germanic umlaut, that involves the raising of mid and low stressed vowels (Table 1) when they are followed by unstressed high vowels, /i/ or /u/.

Table 2 Castro dei Volsci inflectional metaphony

	SING	*PL*	
MASC	ʃp**u**sə	ʃp**u**sə	< lat. *spōnsa*(*m*) 'spouse'
FEM	ʃp**o**sa	ʃp**o**sə	
MASC	s**i**kkə	s**i**kkə	<lat. *sĭccu*(*m*) 'dry'
FEM	s**e**kka	s**e**kkə	
MASC	n**wo**və	n**wo**və	< lat. *nŏvu*(*m*) 'new'
FEM	nɔva	nɔvə	
MASC	v**je**kkjə	v**je**kkjə	<lat. *věclu*(*m*) 'old'
FEM	vɛkkja	vɛkkjə	
MASC	**a**wtə	ɛwtə	<lat. *ăltu*(*m*) 'high'
FEM	**a**wta	**a**wtə	

The vocalic alternation resulting from metaphony fulfills a morphological function in that it marks number and gender in noun declension and grammatical person in verb inflection. In some dialects, a neutralizing sound change merges to schwa the vowels that originally caused the metaphony, and metaphony therefore becomes the sole indicator of the morphosyntactic categories, as shown in the example below taken from a Southern dialect (Table 2 Castro dei Volsci, adapted by Maiden, 1991: 166).

The study identifies 16 subtypes of metaphonesis across Italian dialects, differentiated by the height of the input vowel, the structure of the tonic syllable, and the frontness of the conditioning vowel. Based on these parameters, a set of implicational hierarchies of susceptibility to metaphonic assimilation is found crossdialectally: metaphony by /u/ implies metaphony by /i/; metaphony of lower vowels generally implies metaphony of higher vowels; metaphony in closed syllables implies metaphony in open syllables. These hierarchies reflect inherent properties of the phonetic process and it is shown that the morphologization of metaphonesis precedes the neutralization of posttonic vowels, but it occurs prior to the disappearance of metaphonesis as a phonetic process. One of the aims of the study is to prove the intimate synchronic interaction between phonology (phonetic) and morphology, an interaction that is also relevant for the speaker's own interpretation of the language, where the speaker is obviously an ideal speaker. Maiden states that "... morphonology is an interaction such that morphological structures contribute to the integration of phonetic process into a language."

This detailed study seems to be based on data extracted only from the descriptive dialectological literature on Italian metaphony, without including any fieldwork. This kind of data has presumably been elicited using linguistic questionnaires and so does not include spoken discourse, and probably it is not really reliable when it comes to the quality of the documentation regarding specific phonetic details.

Recent studies of some Campanian dialects (Milano, 2002) confirm the implicational hierarchies discovered by Maiden, but, being based on corpora of spontaneous spoken dialects, they allow us to observe some features that cannot be seen using written corpora or questionnaires about lexical usage. In fact, it is shown that during spontaneous speech there are other sporadic instances of palatalized sounds (a phenomenon similar to the one reported in Table 2, line 5), even in nonmetaphonetic contexts (i.e., in the absence of a following unstressed high vowel), and which are not associated with the morphosyntactic categories of gender and number (i.e., ['vɛrkə] <late Lat. *barca*(*m*) 'boat,' [kra'vɛttə] <Fr. *cravate* 'tie'). Furthermore, the palatalized alternant occurs only in a very small number of lexical items. These two findings might make us question whether the phonetic conditioning of this phenomenon is still productive and whether it continues to be morphologically relevant for the speaker's own analysis of the language. They highlight the synchronic relevance of lexical distribution and a partial synchronic fossilization of the phenomenon.

In other cases, the analysis of actual interactions shows that the production of some alternants in a context of morphophonolgical variability may be affected by factors such as certain discourse features, topic of conversation, particular sociolinguistic identity and idiosyncrasies of the speaker, and other aspects such as linguistic consciousness (Como, 2004).

One can, therefore, analyze morphophonological phenomena in discourse from the perspective of sociolinguistics or of language change, as well as from variationist perspectives. For instance, Holes (1986) works on data from natural conversations of a group of 87 literate and illiterate speakers of the Arabic varieties of Bahrain, in a social context of rapid modernization. He considers morphophonological alternants occurring in the verbal paradigm of some spoken Arabic dialects of Bahrain. The study focuses on the sociolinguistic value of the alternation and on variation connected to subject matter, the situation, and speaker identity and motivation for the spread of change.

One can find interesting evidence about morphophonological change, connected to the spoken nature of language, in Pidgin and Creole studies. Romaine (1992: 31) goes so far as to say that "the most striking differences between native speakers and non-native speakers are probably to be found in the morphophonemics." Samarin (1997), questioning this assumption, examines the process of morphophonological condensation (or reduction) of words in the creolization process of Sango, a nativized pidgin of the Central African Republic. Samarin calls into question explanations of reduction phenomena that are based on speaker intention, nativization, fluency, speed of production, naturalness, and style.

Spoken Discourse: Types

G Pianese, Naples, Italy

© 2006 Elsevier Ltd. All rights reserved.

Introduction

By definition, spoken discourse consists of at least two people taking turns who interact in an initiation and response structure (Sinclair and Coulthard, 1992). Some of the most typical features of spoken discourse are personal involvement and real-time constraints. Involvement is generally marked by using first and second personal pronouns; by monitoring the communication channel through rising intonation, pauses, requests for back-channel responses; by giving emphasis to people and their relationship; by reporting speakers' mental processes and by using emphatic particles (*really*, *just*, etc.). Real-time constraints, on the other hand, are highlighted by place and time adverbs, or by verb tense and aspect (Biber, 1986; Tannen, 1982). This description of spoken texts emphasizes the contrast with written texts, which may also be represented by the following oppositions: involvement vs. detachment; maximal use of context vs. maximal background information; inexplicitness vs. explicitness; dependence for effect of paralinguistic and nonverbal channel vs. dependence on lexicalization to establish cohesion; and so on (Tannen, 1982).

Spoken discourse features are not determined by contrast to written discourse features alone. As the range of variation of spoken texts is so great, from trivial conversation to elaborate political speeches, etc., reference is made to a typology of spoken discourse. Discourse types are characterized by different uses of linguistic structures, refer to specific social contexts and situations, to participants having specific roles and status, and are controlled by social rules and conventions.

The main problem with assigning type labels to discourse is whether it should be classified from a structural or from a functional point of view. Researchers have questioned which of the two perspectives is more relevant in a typology of spoken discourse. On one hand, all utterances have a meaning, a purpose, or an intention (the functions of the utterances). On the other hand, the words in the utterance, the linguistic structure, determine its functions. More often than not, the only way to understand the function of the utterance is by referring to situation, discourse structure, and intonation, whereas the linguistic structure of the utterance is the least helpful in this respect.

The next section briefly explores these different approaches. Here, we will use *text* and *discourse* as synonyms. In fact, the two terms have a different background of uses in linguistic studies. According to Virtaten (1990: 447), "*text* is often used of a static concept – the product of a process – while *discourse* is used to refer to a dynamic notion – the process of text production and comprehension. It is the processual approach that naturally takes situational context into account."

Introduction

By definition, spoken discourse consists of at least two people taking turns who interact in an initiation and response structure (Sinclair and Coulthard, 1992). Some of the most typical features of spoken discourse are personal involvement and real-time constraints. Involvement is generally marked by using first and second personal pronouns; by monitoring the communication channel through rising intonation, pauses, requests for back-channel responses; by giving emphasis to people and their relationship; by reporting speakers' mental processes and by using emphatic particles (*really*, *just*, etc.). Real-time constraints, on the other hand, are highlighted by place and time adverbs, or by verb tense and aspect (Biber, 1986; Tannen, 1982). This description of spoken texts emphasizes the contrast with written texts, which may also be represented by the following oppositions: involvement vs. detachment; maximal use of context vs. maximal background information; inexplicitness vs. explicitness; dependence for effect of paralinguistic and nonverbal channel vs. dependence on lexicalization to establish cohesion; and so on (Tannen, 1982).

Spoken discourse features are not determined by contrast to written discourse features alone. As the range of variation of spoken texts is so great, from trivial conversation to elaborate political speeches, etc., reference is made to a typology of spoken discourse. Discourse types are characterized by different uses of linguistic structures, refer to specific social contexts and situations, to participants having specific roles and status, and are controlled by social rules and conventions.

The main problem with assigning type labels to discourse is whether it should be classified from a structural or from a functional point of view. Researchers have questioned which of the two perspectives is more relevant in a typology of spoken discourse. On one hand, all utterances have a meaning, a purpose, or an intention (the functions of the utterances). On the other hand, the words in the utterance, the linguistic structure, determine its functions. More often than not, the only way to understand the function of the utterance is by referring to situation, discourse structure, and intonation, whereas the linguistic structure of the utterance is the least helpful in this respect.

The next section briefly explores these different approaches. Here, we will use *text* and *discourse* as synonyms. In fact, the two terms have a different background of uses in linguistic studies. According to Virtaten (1990: 447), "*text* is often used of a static concept – the product of a process – while *discourse* is used to refer to a dynamic notion – the process of text production and comprehension. It is the processual approach that naturally takes situational context into account."

Types of Spoken Discourse: A Review of Functional and Structural Approaches

Over the last few years, many studies have attempted to determine the nature and extent of structural and

functional similarities and differences between spoken and written texts, in order to provide some theoretical and empirical prerequisites for comparative discourse research.

Traditionally, and according to rhetorical theory, four basic kinds of discourse exist: narration, description, exposition, and argumentation (De Beaugrande, 1981; Werlich, 1983). These theories emphasize the functional aspects, and the different kinds of speaker contributions are considered prominent. Levelt states that one of the most important features in a typology of texts is the mutual agreement that interlocutors have in the interaction. Levelt (1989: 111–112) affirms that it would be a problem if a speaker "constructs his messages in the framework of the wrong discourse type – for example, if he takes an examination to be a debate, or air-traffic-control discourse to be everyday conversation." Discourse type is established by considering the way the talk is led; for instance if a person talks like a doctor (i.e., speaking of hematoma instead of a bruise) the interlocutor recognizes that the discourse is of the doctor–patient type.

Considering this, Levelt lists some of the different types of discourse as follows: informal everyday conversation, narrations, lectures, examinations and interviews, debates, planning discourse, route direction, radio talk, and therapeutic discourse. One of the main characteristics of informal everyday conversation is "the interlocutors' awareness of informality, of roughly equal rights to the floor, and of the freedom to change topic" (Levelt, 1989: 111). One of the most remarkable differences between informal and formal discourse concerns the turn-taking rules to follow. Heritage (1998: 164) observes that in analyzing interactions one should immediately consider if they involve the use of a special turn-taking organization. In institutional interaction, we normally have a turn-taking organization and the types of contributions speakers are expected to make can be predictable. Consequently, departures from it can be explicitly sanctioned, such as "in meetings when speakers are ruled 'out of order', in the courts when persons are sanctioned for answering when they should not, or failing to answer appropriately, or when children in classrooms are punished for 'shouting out' answers, or talking when the teacher is talking" (Heritage, 1998: 165).

Informal everyday conversation is a label under which many other sublabels could be included. The range of informal everyday conversation is indeed very wide: from chatting with peers to chatting with parents or children, from male to female ways of chatting; from narrations to dialogues, etc. There are some considerable differences between male and female discourse. According to Tannen (1992), one of the greatest differences is the way they report facts: women complain that men tend to tell only the indispensable, whereas men complain that women give too much useless information (see also Carter *et al.*, 2003: 286–287). Tannen thinks this happens because men and women have different approaches to narrations: men see the recounting of incidents as a reporting, while women pay more attention to the metamessage because they feel that recounting experiences is a way to relate to the listener. Another difference between male and female discourse is represented by what Kendall and Tannen (2001: 555) refer to as the taking up of roles of expertise or authority. Men tend to take up this role very often, while women are more likely to avoid it.

An important feature of narrations is interlocutor awareness of the following: "a single speaker has a preferential right to the floor until the narrative is completed. The speaker can count on the suspension of disruptive self-selection by other participants, but has to pay by having to generate a structured sequence of messages" (Levelt, 1989: 111).

A more formal type of discourse includes lectures, examinations, interviews, and debates. Levelt (1989: 112) defines lectures as more serious and impersonal, remarking that when lecturing the speaker is supposed to make his views known to a "spatially marked audience." Examinations and interviews are instead "characterized by a fixed question-answer turn order, in which roles are clearly divided as to who does the questioning and who gives the answers" (Levelt, 1989: 112). Debates are considered to "share much of the question-answer nature of examinations, but the role of questioner is now equally distributed between the participants, and each participant has some thesis to defend" (Levelt, 1989: 112).

The informal vs. formal conversation opposition may also be referred to in terms of institutional vs. noninstitutional interaction. According to Heritage (1998: 164, 175), some features of institutional interaction are the asymmetries of participation and the involvement of the participants in specific goal orientations connected to their institutional identities: doctor and patient, teacher and pupil, etc. For example, in a medical setting, Tannen and Wallat (1993) observed information exchanges between a mother, a child, and a pediatrician. Results showed that the pediatrician used three different registers depending on the three different audiences. She switched from one code to another, using different intonation, voice quality, content, and lexical and syntactic structures. The register used when addressing colleagues and performing diagnostic procedures can be defined as

reporting. It was characterized by flat intonation, rapid rate of speech, relatively low pitch, and the absence of marked facial expressions and gestures. However, when addressing the child she used motherese, as in the following example:

> Doctor: Let me look in your ear. Okay? Do you have a monkey in your ear?
> Child: [laughing] No.
> Doctor: No? . . . Let's see . . . I see . . . a birdie. (Tannen and Wallat, 1993: 39)

Finally, she used everyday conversation register when addressing the mother:

> Mother: It just appears that way?
> Doctor: Yes. It's very . . . it's really . . . it's like floppy you know and that's why it sounds . . . the way it is.
> Mother: She worries me at night (Tannen and Wallat, 1993: 39).

Tannen and Wallat also noticed that the pediatrician suppressed her emotional responses and monitored the amounts and the impact of information imparted. Emotional response to a medical problem by a friend is quite appropriate, whereas a doctor's emotional response could cause the patient to panic.

Another way speakers adapt to institutional contexts is by selecting descriptive terms. For instance, one could use 'cop' in everyday conversation, but when giving evidence in court one would select 'police officer' instead (Sacks, 1979). In medicine, where references to pain are often euphemistic, a patient will be asked 'Is it sore?' instead of 'Is it painful?' (Heritage and Sorjonen, 1994: 174).

The typologies described so far give priority to functional rather than structural analysis: first functional characteristics are isolated, and only later linguistic features are identified on the basis of the predefined functional distinctions. As opposed to this methodology, Biber (1988: 13) noted that even if a set of texts have similar functions, texts may not necessarily have similar forms. On the contrary, if texts share similar linguistic features, they are also expected to have functional similarities, "because linguistic cooccurrence reflects shared function. The order analysis is reversed from previous studies, however. The types are first identified on the basis of their linguistic characteristics and only subsequently interpreted functionally" (Biber, 1989: 4). Biber (1995: 320) also marked the salient difference between text types and registers, and highlighted the linguistic predominance in identifying text types. He noticed that text types are similar to registers in that they "both can be described with respect to their linguistic characteristics and with respect to their situational/functional characteristics. However, these two constructs differ in their primary bases: registers are defined in terms of situational/functional characteristics, while text types are defined linguistically."

His new approach to identifying text types is based on sets of syntactic and lexical features that frequently co-occur in texts. He calls these feature sets, empirically identified dimensions of variation, and the linguistic characteristics of any given text can be specified precisely with respect to each dimension. The dimensions and associated text characterizations provide the basis for his typology. According to Biber (1989: 7), there are 16 main grammatical categories that the linguistic features fall into:

> (A) tense and aspect markers, (B) place and time adverbial, (C) pronouns and pro-verbs, (D) questions, (E) nominal forms, (F) passives, (G) stative forms, (H) subordination features, (I) prepositional phrase, adjectives, and adverbs (J) lexical specificity, (K) lexical classes, (L) modals, (M) specialized verb classes, (N) reduced forms and dispreferred structures, (O) coordination, and (P) negation.

After preliminary analysis, he identifies the five-dimension system to represent communicative functions, in order to deal with all text types (e.g., face-to-face, telephone and public conversation, debates, interviews, broadcast, spontaneous speech, and planned speech). The five dimensions are labelled as follows (Biber, 1989: 10):

1. Involved vs. informational production
2. Narrative versus non-narrative concerns
3. Elaborated vs. situation-dependent reference
4. Overt expression of persuasion
5. Abstract vs. nonabstract style.

He uses quantitative techniques to identify the groups of features that co-occur in texts, and then groupings are interpreted in functional terms. However, Biber (1989: 41) underlines the continuous range of variation among texts and the different score the text may have on each dimension, in a continuous, multidimensional space of variation.

In order to handle this lack of balance between linguistic structure and function, Sinclair and Coulthard (1992) developed a model for spoken discourse analysis, using Austin's speech act theory and Halliday's description of grammar based on a rank scale (they were inspired by Halliday [1961]. Their model first appeared in Sinclair and Coulthard [1975], *Towards an analysis of discourse: the English used by teachers and pupils*, and then in Sinclair and Coulthard [1992]). Sinclair and Coulthard aimed at making a practical and functional description of discourse. They began with classroom settings because of their simple interaction

patterns, and similar discourse rules with other situations, thus creating a system suitable for all discourse analysis. Sinclair and Coulthard observed that in classrooms, the teacher initiated (I) all exchanges, the students responded (R), and the teacher would follow-up (F) on what had been said or done, creating an I-R-F type of discourse. This system is useful as it focuses on the speaker tactics used to determine the purpose of utterances. They define lessons as the greatest unit of classroom discourse, consisting of more transactions formed by the boundary elements, the 'frame': *right*, *well*, *good*, *OK*, *now*. These terms are frequently used by all teachers, and mark the end of one stage and the beginning of the next. The function of the 'focus' (a special kind of statement) in the transaction is to tell the class what is going to happen; and they generally occur after frames. Sinclair and Coulthard are aware that the order of transactions varies for each teacher and there is no restriction on the occurrence of different types.

Types have no defined boundaries; on the contrary, they are characterized by a continuous range of variation, which can be grasped only when observing concrete data. It is impossible to label types without data. Theoretical findings do not always reflect what in effect happens in practice. For example, Basturkmen (2003: 21–22) has investigated the ways the presence and absence of the tutor impacted on the exchange structure of an academic discussion. In contrast to his expectations, his analysis did not show that the authority figure dominated by controlling the interaction, i.e., by initiating exchanges; on the contrary, during interaction in presence of the tutor, half the exchanges were initiated by students. He also observes that the arrival of the tutor made the discussion become more solution-driven rather than idea focused, with a large number of student–student exchanges.

A further example of spoken discourse is sports broadcasting. According to Ferguson (1983), sports broadcasting shows a particular use of syntax and register. He considers it as a discourse genre and analyzes it in terms of register variation. The register is located by the characterization of its occasions of use – such broadcasts start with background information about the game, the occasion, the teams, and so forth; they include components of direct reportage, comment, advertising commercials, and conclude with interviews of players and coaches. These elements are in relatively fixed proportions and relatively fixed sequence, and selected syntactic characteristics are also identified such as simplification (deletion of copula and sentence initial nominals, which give both the lowering of pitch and loudness for parenthetical expressions and structural simplification), inversions ("Holding up at third is Murphy"; Ferguson, 1983: 160), heavy modifiers ("Eddie Yost, *a crackerjack, who was not a power hitter*, . . ."; Ferguson, 1983: 163), result expressions (*for* + noun "He throws *for* the out"; *to* + phrase "And he just keeps alive, reaching out *to* foul-tip one back"; Ferguson, 1983: 161), routines (e.g., giving the count: "One and one"; Ferguson, 1983: 166).

Conclusion

The list of types of spoken discourse taken into account here is in no way complete. Instead, our aim was to emphasize some critical points related to the problem of establishing the typology of spoken discourse, such as the limits and the indistinct boundary of all kinds of typology, and finally the priority of the functional or structural perspective.

Rather than trying to encourage a tolerant attitude conciliating both approaches, or to establish priorities between them, the old chicken and egg story prevails: the problem is deciding which comes first? "The situation we're in (e.g., a committee meeting)? Or the language we use (our committee ways of talking and interacting)?" (Gee, 2003: 11). According to Gee, this reciprocal process through time is just the core of the magic property of language: "when we speak or write we craft what we have to say to *fit* the situation or context in which we are communicating. But, at the same time, how we speak or write *creates* that very situation or context" (Gee, 2003: 11).

Spoken Discourse: Word Order

O Yokoyama, University of California, Los Angeles, CA, USA

© 2006 Elsevier Ltd. All rights reserved.

A fundamental empirical step in the analysis of word order (WO) in spoken discourse is that of determining the scope of the verbal material within which the order of elements is to be considered. The problem is particularly difficult because spoken material typically appears in patterns that deviate from the 'well-formed' syntactic structures of written language. This deviation can be seen – along the lines of the classical generative focus on syntactic competence – as merely performance based, and too trivial to analyze; or as nontrivial and generated by discourse-conditioned syntactic rules operating on 'well-formed' structures (e.g., discourse deletion rules, as proposed by functionally oriented syntacticians), or it may be – as more recently argued by an increasing number of scholars (cf., Sornicola, 1991; Haiman and Thompson, 1988; Miller and Weinert, 1998) – that spoken structures, with their fragmented syntax, may require an entirely different clause-based (rather than sentence-based) approach to syntax.

Another immediate problem for the student of spoken discourse lies in the terms in which spoken WO is to be formulated. One formulation frequently used by linguists is based on the Greenbergian categories of S(ubject), V(erb), and O(bject) (Greenberg, 1966). The familiar WO universals, however, were explicitly formulated so as to exclude 'marked' sentences: they were based on sentences without pronouns, without missing arguments, and on sentences uttered with 'neutral' intonation. Since this excludes precisely the phenomena typical of spoken language, the regularities that characterize spoken WO are unlikely to emerge from using these categories. The other well-known formulation of the linear order of elements operates with the Prague school

Spoken Discourse: Word Order

O Yokoyama, University of California, Los Angeles, CA, USA

© 2006 Elsevier Ltd. All rights reserved.

A fundamental empirical step in the analysis of word order (WO) in spoken discourse is that of determining the scope of the verbal material within which the order of elements is to be considered. The problem is particularly difficult because spoken material typically appears in patterns that deviate from the 'well-formed' syntactic structures of written language. This deviation can be seen – along the lines of the classical generative focus on syntactic competence – as merely performance based, and too trivial to analyze; or as nontrivial and generated by discourse-conditioned syntactic rules operating on 'well-formed' structures (e.g., discourse deletion rules, as proposed by functionally oriented syntacticians), or it may be – as more recently argued by an increasing number of scholars (cf., Sornicola, 1991; Haiman and Thompson, 1988; Miller and Weinert, 1998) – that spoken structures, with their fragmented syntax, may require an entirely different clause-based (rather than sentence-based) approach to syntax.

Another immediate problem for the student of spoken discourse lies in the terms in which spoken WO is to be formulated. One formulation frequently used by linguists is based on the Greenbergian categories of S(ubject), V(erb), and O(bject) (Greenberg, 1966). The familiar WO universals, however, were explicitly formulated so as to exclude 'marked' sentences: they were based on sentences without pronouns, without missing arguments, and on sentences uttered with 'neutral' intonation. Since this excludes precisely the phenomena typical of spoken language, the regularities that characterize spoken WO are unlikely to emerge from using these categories. The other well-known formulation of the linear order of elements operates with the Prague school

functional categories (now perhaps more appropriately called cognitive categories) often referred to as 'old/new information,' 'topic/comment,' or 'theme/rheme.' The original Praguian analysis of WO in terms of these categories was carried out mainly on the literary register of Slavic languages and English, as found in written sources. It has since been applied to spoken material, with the inclusion of intonational factors. The tendency to begin an utterance with a topiclike argument group and continuing with a proposition or a comment about this topic has by now been attested in a number of Indo-European 'subject languages,' and it appears to be the main linearization principle in so-called 'topic languages' (Li, 1976). It has also been shown (Ochs, 1979) that this order is typical of the speech of English-speaking children. Since both the study of natural spoken communication and cognitive linguistics are young areas, however, caution must be exercised in formulating WO rules in terms of concepts that await consistent, or at least generally accepted, definitions.

Spoken discourse by definition involves utterance intonation, and therein lies another challenge for WO analysis. Intonation happens to be the youngest area of phonology, and it is difficult to incorporate it into analysis without considerable expertise. Crossdisciplinary expertise, however, is relatively rare; consequently, important intonational cues affecting WO are often overlooked, as intonation goes misjudged, underplayed, or outright ignored in the analysis of WO. Moreover, a prerequisite for intonationally valid analyses is access to reliable auditory data, a factor rapidly becoming addressed but still not standard in spoken WO research.

Spoken language is situated in discourse. WO produced in spoken discourse is affected by a complex interaction of such pragmatic factors as the speaker's assumptions about the interlocutor and about their engagement in discourse, the speaker's subjective judgments and viewpoints, the deictic character of utterance elements, and the role of anaphora. One result of this context dependency is the prevalence in spoken data of elliptical constructions. What sounds like a complete utterance may contain only one or two words, even when the corresponding 'well-formed' sentence in a written or a formal register would have several. In analyzing the order in the spoken utterance, it hardly seems justified to speak of the 'would-be place' of a constituent missing in the spoken structure on the basis of a written version. This factor creates problems for both syntactic analysis and generalizations about WO.

We mentioned above that the source of the original Prague school studies of WO was written language. This is not a trivial point for the analysis of spoken WO, because before selecting the data we must decide how to distinguish spoken language from other varieties of language. The most obvious medium-based opposition – spoken vs. written – is clearly too simplistic. Variation in what is considered a single language can be regional, social, stylistic, idiolectal, or – everything else being equal – it may depend on delicate pragmatic distinctions, such as those of subject matter, the speaker's role in discourse, or the degree of spontaneity vs. preparedness of speech. In languages with a literary and/or normative tradition, the spoken language of some speakers is inevitably contaminated by the literary norm of the written language, which itself may be influenced by literary traditions of times or places far removed from the spoken language under consideration (including literary traditions imported from different language families). Teasing apart the features inherent in spoken and written WOs in a given language requires refined in-depth stylistic, cultural, and historical examination of a kind that has yet to be undertaken with respect to most languages. This raises both the practical question of the sociolinguistic and stylistic parameters used in the selection of the data for the study of spoken WO, and the theoretical question of the role and adequacy of diachronic considerations in the analysis of synchronic states.

We can expect there to be a difference in the occurrence of surface WO variability between languages with grammatically significant WO and those with so-called free WO. In the former, WO freedom within a clause is largely limited to adverbial elements; in the latter, variation is seen in the ordering of all constituents. Our discussion here will center on empirical material from one Indo-European language, Russian, often cited as an example of a 'free WO language.' Russian spoken data began to be actively collected in the late 1950s, predating the massive rise of interest in spoken language in the West by a quarter-century. The term 'spoken Russian' (SR) was firmly established through the appearance of Zemskaia (1973), a comprehensive and still unsurpassed survey of SR, which included a discussion of the salient characteristics of spoken WO (Zemskaia, 1973: 380–402); selected transcripts of the data were published as Zemskaia and Kapanadze (1978). The data were selected with attention to the points mentioned above. They consist of recordings of informal face-to-face conversations and narratives, and as such they represent what Givón (1979a) calls the 'pragmatic mode' of the language; both spontaneous and semirehearsed discourse are included, the latter occurring in ritualized dialogue (e.g., salesperson–customer encounters) and in narratives (Zemskaia distinguishes SR from

planned formal language, written or oral, dubbed 'bookish-literary Russian' [BLR]). Demographically, however, the data were produced almost exclusively by speakers of the literary language, and thus a considerable influence of normative grammar is to be expected. Indeed, the WO in these data shows a mixture of both normative/written and nonnormative/spoken WOs, revealing orders exclusive to SR or those shared by SR and BLR. Audio materials readily available to researchers of SR, however, are rather sparse, Kitaigorodskaia and Rozanova (1995) being one of them. A unique source is found in the growing electronically accessible database of audio texts of different oral genres, speaker ages and dialects of modern Russian edited by Sappok and Bondarko (1988–), which includes spontaneous and semispontaneous dialogue and narratives.

The peculiar syntax of 'spoken style' (as SR was first called) has been recognized since Panov (1962) delivered his forceful defense of spoken language as a legitimate object of linguistic investigation and a system with its own regularities, irreducible to a simplified, sloppy, or corrupted version of literary language. The subject of spoken WO began to be addressed concurrently with the rise of interest in SR (cf., Sirotinina, 1965; Lapteva, 1966; Kovtunova, 1967; and a major treatment in Lapteva, 1976). The question of the units of SR was tackled early on as a prerequisite to syntactic analysis. WO in Zemskaia (1973) is analyzed within so-called utterances, units marked by finite intonation (1973: 217ff.; cf., the intonation-and/or rhythm-based solutions for English in Chafe, 1988, and Halliday, 1989, among others). Based on this definition, (1), for example, is analyzed as three utterances ('//' signifies finite intonation; this and all examples and judgments are those of the sources; for examples from Zemskaia, 1973, only the page number is given in parentheses following the translation; for occasional other sources, examples are followed by full citation information):

(1) ia poslal im // pis'mo // zakaznoe //
I sent them letter registered
'I did send them. A letter. A registered one' (218)

The translation provided here follows Zemskaja's analysis of this message as three utterances. Under this analysis, the first utterance provides evidence of WO regularities within utterance boundaries, while the last two utterances contribute to the study of the sequencing of utterances in SR. It may also be argued, however, that the three utterances are a unit, since they constitute a complete proposition, albeit conveyed as a series of three intonationally independent chunks (compare similar phenomena in children's speech described in Ochs, 1979, or the literary device characteristic of modern prose called 'parcellation'). It may be possible, then, to see the sequence in (1) as a one-unit message, and on that basis try to account for the peculiarities of WO in this message. The way we set unit boundaries thus affects our analysis of WO.

If (1) was a case when intonational boundaries suggested more segmentation than that indicated by propositional considerations, the situation in SR can also be the reverse. An example is (2); taken from a typical SR excerpt in which, according to Zemskaia, only six out of 15 intonationally defined utterances can be analyzed as normative syntactic constructions ('/' signifies nonfinite intonation).

(2) / čto čelovek dolžen khodit' v sutki ne
that man must walk in day not
men'še čem desiat' tysiač šagov delat' //
less than ten thousand steps make
'that one must walk make no less than ten thousand steps a day' (220)

In this utterance fragment, there are two infinitives, 'to walk' and 'to make'; they are separated by several phrases and each of them would be normative with 'must' – but they cannot cooccur in BLR, as they do here. Ignoring intonational cues by positing a clause break after 'walk' and reinterpreting the WO accordingly (i.e., as 'one must walk, [one must] make no less than ten thousand steps a day') would amount to forcing a superficially attractive but incorrect solution. The challenge for the analyst is to determine why, when, and in what order this not uncommon SR pattern occurs (Zemskaia, 1973: 339–347; Lapteva, 1976: 339–351).

Standard literary Russian is often cited as an example of a language that allows different orders of elements within a sentence to satisfy the cognitive 'theme → rheme' requirement. As Sirotinina (1965), Lapteva (1966), Kovtunova (1967), Zemskaia (1973), and others have established early on, however, rhemes in SR are frequently marked not by their sentence-final position but by accentual prominence, and they tend to occur early on in an utterance. Thus the SR utterance (3) would occur in BLR as (4) (we have added here, and elsewhere, when helpful, our own indication of prominent accents, following the autosegmentally oriented approach to Russian intonation suggested in Yokoyama, 2001):

(3) skovoródka upala //
skillet fell
'a/the skillet fell' (249)

(4) upala skovorodka
fell skillet
'a/the skillet fell'

In (3), the rhematic (i.e., newly brought into the current discourse context) subject 'skillet' is accentually prominent (usually bearing a falling pitch accent) and appears first, while in (4), neither word bears accentual prominence and the rhematicity of the subject is encoded in its sentence-final position. The contrast between (3) and (4) shows some of the basic considerations that go into WO analysis in SR: the finite/nonfinite intonational distinction is important for defining the units of analysis, while the presence/absence of accentual prominence is important for at least some WO variation; and the difference between SR and BLR is particularly significant when analyzing WO data. In languages where WO is grammaticalized, the situation may differ. The English translations of (3) and (4), for example, are identical, since VS order is impossible, and in both cases the word 'skillet' must carry a pitch accent, which marks the rhematic element. The difference would have to show up in a different way: a husband may casually explain a noise in the kitchen to his wife as 'A/The skillet fell' (=[3]), while a proper old butler, explaining the same noise to the lady of the house, may deliver the considered response 'A/The skillet has fallen, madam' (=[4]).

The same principle as in (3) applies in longer utterances of SR. Examples (5)–(7) illustrate this, while allowing us to make additional generalizations:

(5) vot krásnoe daite požaluista mne moloko //
PART red give please me milk
'give me that réd milk please' (387)

(6) neveroiátno ėto dlilos' dolgo //
incredibly this lasted long
'this lasted incrédibly long' (388)

(7) otdel'nogo / u nas nét izdaniia //
separate at us is-not edition
'a separate edition we don't have' (391)

In examples (5)–(7), the accentually prominent (as marked) rhematic elements are, respectively, 'red,' 'incredibly,' and *net* 'there isn't.' When such rhematic elements occur early on in a noninterrogatory SR utterance, they may be preceded by items assessed by the speaker as contextually activated; these items carry a rising tone. The accented rhematic element may, in turn, be followed by other material which is unaccented and intonationally indistinct. The contextually activated items here are: the initial *vot*, a deictic particle pointing to the (red) milk carton in (5), and in (7), a group consisting of 'separate,' a contrasted item from the preceding context, and a prepositional phrase involving first-person discourse deixis (an item normally activated in a discourse situation). The postrhematic unaccented portion is a syntactic variable which the speaker evidently treats as informationally lightweight. Syntactic ties are ignored, as the noun phrases 'red milk' and 'separate edition' and the adverbial phrase 'incredibly long' are split by intervening material. Zemskaia states that the rhematic element occurring early in this way can syntactically be part of a noun phrase, an adverbial phrase, an adjective phrase, or a verb phrase (1973: 383ff.). The WO in SR statements observed so far can thus be generalized as follows:

(a) contextually activated items → accentually prominent rhematic item → other items

The concepts 'rhematic' and 'thematic' originated in the analysis of statements, and applying them to nondeclarative sentences is at best difficult. What is uncontroversial, however, is that questions in SR are distinct from those in BLR, in terms of both their intonation and their WO. As opposed to the BLR yes/no question in (8), consider the corresponding SR question (9) (Lapteva's data were hand-recorded and normal punctuation is used; '∨' indicates the boundary between 'two adjacent informational centers,' Lapteva, 1976: 186):

(8) budet li rabotat' professor?
will Q-PTCL work professor
'will the professor work?'

(9) professor ∨ búdet rabotat'?
professor will work
'the professor, will (he) work?' (Lapteva, 1976: 190)

The intonation of (8) is not distinguishable from that of a statement, and its interrogatory nature is understood from the initial position of the question focus (the tense marker) followed by the interrogatory particle *li*. The intonation of (9), on the other hand, is distinctly interrogative, the question focus bearing a rising pitch accent. The first word, 'professor,' bears a falling tone – decidedly not a feature of theme intonation in statements. Lapteva's intuitively defined 'two adjacent informational centers' in yes/no questions of SR evidently refers to the item bearing a falling tone and to the following question focus bearing a rising tone. To be able to refer to them separately, and given the dubious status of concepts such as 'theme' and 'rheme' when applied to questions, I will call the element occurring early on in SR questions of this type with a falling tone the 'q-item.' The q-item in (9) is referentially known to the interlocutors, but this is not a requirement for q-items. This is illustrated in (10), a yes/no question of essentially

the same structure as (9); here, the q-item 'pencil' is clearly new to the discourse situation and the speaker has no referential knowledge of it:

(10) u vas karandasha ∨ nét blizko pod rukami?
at you pencil is-not close at hands
'you don't have a pencil around (by any chance)?'
(Lapteva, 1976: 190)

Examples (10) and (11)–(13) provide additional evidence about interrogatory WO in SR. In (10)–(13), the q-items are not utterance initial; they follow discourse-contextually activated items: in (11), a referentially known personal name (either objectively brought up in the preceding context or subjectively assumed by the speaker to be of concern to the addressee at the moment), and in (10) and (12)–(13), the second-person discourse deixis (normally activated in a discourse situation). A q-item can also be a whole clause, as in (11). The foci of these yes/no questions (marked with pitch accents) occur after the q-items and can be followed by variables, including the clauses to which the q-items syntactically belong, as in (12) and (13):

(11) Ženia čto zavtra edem znáet?
Zhenia that tomorrow we-will-go knows
'does Zhenia know that we're going tomorrow?' (401)

(12) ty musor slýšala kogda uvozili?
you garbage heard when they-took
'you heard when they took the garbage?' (399)

(13) tebe sobaka nrávitsia kogda v dome?
to-you dog appeals when in house
'do you like when there's a dog in the house?' (400)

In (11), the whole clause 'that we're going tomorrow' appears early on, and within this q-item clause, *zavtra* 'tomorrow' occurs early bearing a falling tone, similar to the way the accentually prominent rhematic items occurred early on in (5)–(7). The WO in typical SR yes/no questions such as (9)–(13) can then be described as:

(b) contextually activated items → q-item → question-focus → other items

Note the similarity with (a). The WO in SR wh-questions operates the same way as in (b).

We mentioned at the beginning that one of the challenges for the analysis of WO in spoken discourse is to find appropriate terms in which to formulate the order. It is evident from cases such as (5)–(7) with early rhemes, and from cases such as (9)–(13) with q-items, that WO cannot be described in terms of syntactic units, as in both groups syntactic ties are violated and syntactic units are broken up. In contrast, viewing WO in terms of cognitive categories, and in conjunction with intonation, allows us to make some meaningful generalizations about SR WO patterns that are similar in both statements and questions. If we look at the behavior of contextually activated items, we see that they, too, show consistency when viewed in cognitive terms; consider the patterns in (14)–(17):

(14) bananovyi sok / nevkusno //
banana juice untasty
'banana juice, it doesn't taste good' (258)

(15) Validol nigde v gorode net //
Validol nowhere in town is-not
'Validol, it's nowhere in town' (258)

(16) ėta sumka / podkladka moetsia //
this bag lining washes
'this bag, the lining is washable' (252)

(17) a u nas iantar' / bróšechka
and at us amber broochlet
odna skol'ko stoit //
one how-much costs
'and our amber, just a tiny pin costs a lot!' (313)

In these utterances, there is no syntactic connection between the contextually activated items that appear in the beginning and the following material (note that despite the translations, there are no resumptive pronouns in the Russian originals). Example (14) lacks the expected gender–number agreement between the masculine nominative phrase 'banana juice' and the neuter impersonal predicate, while in (15), 'Validol' (a medicine) appears in the nominative case instead of the syntactically required genitive. In (16) and (17) the initial phrases, which bear nonfinite intonation, are simply linearly linked to complete sentential structures on their right. This relationship closely resembles so-called 'double subject' constructions, extensively documented for Korean and Japanese (e.g., Kuno, 1973). In these languages, the utterance-initial nominals syntactically detached from the following complete sentences are not restricted to spoken grammar, while in Russian, this type of linking is limited to spoken discourse. The placement of accentual prominence in (15)–(17) is clearly on the 'broochlet' and (in unmarked situations) on 'nowhere' and 'lining,' making their WO the same as in (a).

The importance of intonation and the role of deletions is very clear from another typical SR pattern seen in (18)–(20):

(18) a kotoraia v tsentre pust' nám otdadut
and which in center let us give
'and (the one) which is in the center, let them give it to us' (Lapteva, 1976: 150)

(19) riadom s oknom segodnia výpisali //
next to window today they-discharged
'(the one) next to the window, they discharged today' (236)

(20) nad nami živut / v Kíev pereezžaiut //
above us live to Kiev move
'(people) live above us, they're moving to Kiev' (239)

When considered without intonational clues, these sequences are syntactically and semantically implausible (note that despite the translations, there are no resumptive pronouns in the Russian originals). Yet constructions like these are frequent in SR and regularly interpretable as statements about the utterance-initial items (bearing the rising tone typically assigned to thematic material) which serve as arguments (but not necessarily as grammatical subjects) of the following incomplete clauses. Once these factors are taken into consideration, the WO in these constructions can be described. Despite its variable structure (in [18]–[20], respectively, a headless relative clause, a prepositional phrase, and a verb phrase), the front material as a whole is contextually activated, and the order in (18)–(20) is basically the same as in (a).

The extremely common SR pattern illustrated in (21) shows that the same constructions occur in questions. In this yes/no question, the prepositional phrase that functions as the subject of the following verb is its q-item, as is corroborated by the falling tone on 'sled,' while the rising pitch accent is on the question focus (the verb). Once the missing material and the intonational and cognitive cues are taken into consideration, the WO in questions with this SR structure turns out to be parallel to that in (b):

(21) s sankami ne prokhodíl tut?
with sled not passed here
'anybody with a sled passed here?' (236)

In SR, as in other spoken languages, the contextually activated utterance-initial material, regardless of its syntactic structure, may occur with resumptive nouns or pronouns in the following portion, as in (22)–(24):

(22) kartoška / kartošku on ne est //
potato.NOM potato.ACC he not eats
'potatoes, he doesn't eat potatoes' (243)

(23) s vami obedala / kak eë familiia?
with you lunched what her name
'the woman who had lunch with you, what's her last name?' (239)

(24) a respondent / ėto čto?
and respondent this what
'and "respondent," that's what?' (Zemskaia and Kapanadze, 1978: 73)

The resumptive elements do not necessarily duplicate the grammatical case of the front material. In the wh-questions (23) and (24), the first clauses constitute q-items, and the following sentences contain pronouns coreferent with the contextually activated material; in contrast with yes/no questions, the direction of the pitch in the wh-word – the question focus – is falling. The WO in (23) and (24) is the same as that in (9)–(13).

As can be seen from (24), the position of wh-words in SR can be clause final; in (24), the wh-word follows a deictic pronoun *ėto* 'this.' In BLR, the wh-word would appear in the beginning of the question and with a rising tone: *Chto takoe 'respondent'?* 'What is a "respondent"?'

Judging from the examples in Zemskaia (1973), Lapteva (1976), and Zemskaia and Kapanadze (1978), constructions with resumptive nouns or pronouns, which are similar to English left dislocation and French cleft constructions such as *moi, j'sais pas* '(as for) me, I don't know,' often occur in dialogues, and the contextually activated item repeats an item mentioned in the preceding utterance by the interlocutor. This suggests that their function may be to create an explicit discourse linkage in dialogic pairs.

Besides left dislocation, SR is known to have so-called right dislocation. The resumptive material on the right is unaccented, and it differs from the SR left dislocation in that the grammatical case of the added noun phrase is the same as that of the pronoun in the preceding clause; consider (25):

(25) oni vsé takie igolki
they all such needles
'they're all like that, needles' (Lapteva, 1976: 184)

Occasionally, the added noun phrase, still unaccented, appears in appositionlike fashion inside the main clause and immediately after the pronoun. The WO in these utterances follows the pattern in (a).

To summarize (a) and (b), then, the WO of SR utterances defined as sequences ending in finite intonation can be characterized intonationally as material with rising tone → accentual prominence → no accent. In terms of content, these are utterances with a one-unit message, corresponding in normative written grammar to simple sentences with a single proposition and possibly with a relative clause. Cognitively, items with rising tone are either

objectively or subjectively contextually activated; items with accentual prominence are rhematic (in statements) or consist of a sequence of a q-item and a question focus (in questions); and items with no accent are informational lightweights.

We now turn briefly to SR cases roughly corresponding to subordinate constructions in BLR. These usually involve two propositions and imply (but do not necessarily indicate syntactically or morphologically) a temporal, causal, conditional, or some other relationship between them. The WO within each sentence or clause is the same as just summarized, and what is of interest to us here is the relative ordering between the two propositions. When asyndetic, the 'subordinate' clause in SR usually follows the 'main' clause or occurs in the middle of it, as in (26)–(29):

(26) im očen' ponravilos' / v Rige byli //
to-them very appealed in Riga were
'everything was great, they were in Riga' (321)

(27) ia v bol'nitsu zub bolit edu //
I to hospital tooth hurts go
'I'm going to the hospital, my tooth hurts' (325)

(28) lekarstvo-to ia poidu kak nazyvaetsia?
*medicine-*PART *I will-go how called*
'the medicine, I'm going, what's it called?' (328)

(29) gorčitsy v tri ia zakhodil net //
mustard in three I stopped is-not
'mustard, I stopped at three [stores], is nowhere' (337)

The motivation for choosing between postposition, interposition, or occasional preposition of the 'subordinate' clause is not clear. According to Zemskaia (1973: 318–319), there are intonational signs of subordination between the two propositions: the subordinated clause has a faster rhythm and sometimes one of the two clauses is uttered with a lower pitch. Perhaps the clearest sign of subordination is semantic. As Zemskaia (1976: 329) points out, the semantic relationship between the two linked clauses may not have exact equivalents in BLR, as in (28), where no subordinate BLR paraphrase is available. This would mean that SR has not only its own prosody and WO rules, but also its own logic and semantics. The problem of the relative order of the two propositions requires further research.

Subordination in SR sometimes occurs with conjunctions or complementizers, just as in BLR. Their position, however, is not limited to the normative position between the two sentences:

(30) khólodno véter potomu čto
cold wind because
'it's cold, because there's wind' (394)

(31) dovól'na ty gósti prikhodiat k pape kogda?
glad you guests come to papa when
'are you glad when visitors come to dad?' (395)

(32) my v kino ne uspeem /
we to cinema not make
on esli pridet pozdno //
he if comes late
'we won't make it to the movies if he comes late' (397)

Very little has been done with the analysis of such orders. Using the above criteria, it can be observed that an early occurrence of rhematic items in the subordinate clause results in their being placed right after the main clause, leaving the conjunction or complementizer stranded at the end in (30) and (31); this is similar to the way some conjunctions occur utterance finally in Japanese (cf., the Japanese equivalent of [30]: *samui, kaze da kara* '[lit.] cold, wind is because'). In (32), it is the contextually activated element 'he' that takes linear precedence over the conjunction. Using the same cognitive categories while paying attention to the intonational properties of the material may well be a promising strategy for further elucidation of this type of SR subordination.

The SR material discussed above illustrates many of the theoretical and methodological points that are fundamental to the analysis of WO in discourse, an area of research that incorporates several different disciplines. Indeed, the fields of knowledge pertinent to the study of spoken WO have not been exhausted by the considerations offered here, as some data (cases such as [2], for example) point to the need for exploring instrumentally the linearity of attention shifts and our ability to maintain attention on a given event or situation. Further progress in the study of the complex problems posed by WO in spoken language will therefore depend crucially on interdisciplinary cooperation.

Spoken Document Retrieval, Automatic

A Hauptmann, Carnegie Mellon University, Pittsburgh, PA, USA

© 2006 Elsevier Ltd. All rights reserved.

What Is Automatic Spoken Document Retrieval?

Spoken document retrieval (SDR) aims to provide content-based retrieval of passages from archives of recordings of speech. Thus, SDR refers to the retrieval of spoken material in digital audio files, ordered by relevance to some textual query. In the most common realization, the query consists of a typed sequence of words, a question, or a statement of information need. The spoken documents are previously indexed audio recordings of human speech, which were automatically transcribed by a speech recognition system. The goal of SDR, therefore, is a form of information retrieval – that is, automatically finding those complete documents or excerpts that either directly contain the words and expressions in the query or that are semantically relevant to the information need. Thus, the speech transcription has to be automatic and the retrieval has to be based on a user-supplied query. Retrieval of music, songs, or nonlanguage sounds does not fall into the category of spoken document retrieval. Concise question–answering, where a user would expect to hear a short answer to a question as opposed to being presented with a complete audio document, is also not considered part of the definition of automatic SDR.

The purpose for developing mechanisms that provide access to spoken information is fairly obvious. The availability of inexpensive computers, storage devices, and high-bandwidth transmission capacity has resulted in many large multimedia collections. People have become accustomed to full access to virtually all textual information available on the Internet. Without SDR, access to audio archives, or at least spoken audio collections, would be restricted to those limited documents that have been manually transcribed or indexed with key words. Although a significant fraction of current television and radio broadcasts have manually created transcripts or at least approximate script outlines, a much larger amount of spoken audio recordings are untranscribed because the cost of human transcription is too

high relative to the potential useful value or because they consist of older radio and television 'legacy' productions, for which transcripts were lost or never created.

SDR creates a full search and retrieval capability in a way that is already widely available for text content. This capability is useful in applications such as

- Searching the transcripts of video conferences.
- Accessing portions of taped educational lectures.
- Finding specific content in training audio and video.
- Organizing archived voice mail by spoken content.
- Accessing news of interest from television or radio.
- Archiving meetings as a form of corporate memory and documentation.
- Retrieving audio transcripts from sports and entertainment broadcasts, including practically any talk shows, films, quiz programs, etc. with a significant spoken component.

Problems arise in SDR from insufficient fidelity of the speech recognition transcript, the accuracy of the retrieval matching between the query and the transcript, and the lack of segmentation (i.e., the absence of clear document, story, or passage boundaries in continuously recorded audio streams).

The Basic Approach to SDR

As the first step, an SDR system generates a text transcript from the audio recordings to enable text-based retrieval over these audio documents. The idea is to first apply automatic speech recognition to the audio documents to obtain a text transcript. The transcript recognition units are usually words; however, syllables and phonemes have also been used. Each word in the transcript is marked with the time at which it occurred. In general, SDR is designed to search vast archives of audio documents that have been previously indexed. In the case of a stable collection of audio recordings, speech recognition occurs once before the archive is indexed. In archives that are actively accumulating spoken documents, speech recognition is performed on a continuous basis as the audio stream is captured and saved.

The next phase in the SDR process is information retrieval index creation. To facilitate matching root words with different inflections and morphologies, a stemming process converts all speech-recognized words into their canonical root stems. After removing very frequently occurring words, the so-called 'stopwords,' the remaining word stems are compiled into an inverted index, which allows fast access. Each word stem constitutes an entry in the index, listing all documents in which it was found, the number of times it occurred in the documents, and the time of each individual occurrence. Statistics are kept on the distribution of the words across the documents in the collection for retrieval similarity ranking.

When the indexed archive is accessed, a query indicating the user's information need is expressed as a sequence of words or syntactically complete sentences. Although queries are typically typed, in some situations the query may also be spoken. In a query preprocessing step, the query orthography is normalized with all punctuation and capitalization removed. Thus, for example, after normalization, stemming, and stopword removal, the query *C.I.A.'s use of spy planes in 1985?* might appear as *CIA SPY PLANE NINETEEN EIGHTY FIVE*. The query is then transformed into a sequence (vector) of units of the same type as the indexed transcript recognition units (i.e., words, syllables, or phonemes).

To retrieve spoken documents relevant to a user query, each document in the archive is automatically compared to the query vector to determine how well the document 'matches' the query. The matching function R(Q, D) computes the relevance (R) of a query (Q) to a document (D). A list of the query-relevant audio documents is then returned to the user, where the locations of the matching words are indicated. The list of audio documents or passages is ordered by decreasing similarity between the query and the content (transcription) of the document (Robertson *et al.*, 1996). A typical SDR process is shown in Figure 1.

Evaluation of SDR

Evaluation of SDR systems can be done along different dimensions. The complete system performance can be measured in terms of how well the SDR system retrieves spoken documents, but there are often useful aspects in measuring the performance of the components, notably the speech recognition, segmentation, and text information retrieval modules.

The complete SDR system performance is usually measured in terms of mean average precision (MAP), a measure also widely used for text information retrieval. 'Precision,' in general, is defined as the number of relevant documents retrieved divided by the number of items retrieved. Average precision is a single valued measure that reflects performance over all relevant documents for a given query, rewarding systems that retrieve relevant documents at high ranks. It is defined as the average of the precision value obtained after each relevant document retrieved. When a relevant document is not retrieved, its precision is set to zero.

Figure 1 The basic architecture of a spoken document retrieval system.

Formally, for a given query, there are a total of N_r items in the collection that are relevant to this query. Assume that the system retrieves k relevant items and they are ranked as $r_1, r_2, \ldots, r_k$. Then, the average precision is computed as

$$AP = \left\{ \sum_{i=1}^{k} i/r_i \right\} / N_r \qquad (1)$$

MAP is the average of the precision values over a set of queries.

Evaluations use a standardized evaluation format, a common corpus (frequently broadcast news), and test data to ensure different systems and their approaches can be compared fairly. The largest SDR evaluations to date were carried out by the National Institute of Standards and Technology, eventually comprising more than 20 000 broadcast news stories (which translated to approximately 500 h of audio), with 50 queries in a typical evaluation 'task' (Garofolo *et al.*, 2000).

Speech recognition is usually evaluated in terms of the word error rate (WER) in the transcript produced by the automatic speech recognizer. It is defined as the sum of the inserted words, deleted words, and substituted words, divided by the total number of words in a 'perfect' human-transcribed reference transcript.

Publications on SDR will occasionally refer to the term error rate (TER) in speech transcripts, which is similar to WER but ignores all information retrieval 'stop words' (usually a list of very common and function words, which do not contribute to the relevance ranking of a document) in the speech transcripts. A variation sometimes referred to as the STER (stemmed term error rate) also collapses all morphological and inflectional variants of a word into the same stem. For example, in the sentence, 'The large apple was very rotten,' if the recognizer produced an output of 'That large apples were very rotten,' the WER would be 50% (3/6), the TER would be 33.3% (1/3, since 'that,' 'were,' and 'very' are stop words and thus ignored), and STER would be 0 (0/3) because the roots for the words 'large,' 'apple,' and 'rotten' were all correctly preserved. Although it can be argued that TER and STER (or even QTER, which only considers actual query words) are more appropriate measures than WER for the assessment of how good the speech recognition is for the purposes of SDR, in practice all these measures are approximately equivalent (Garofolo *et al.*, 2000).

SDR systems performance evaluation is usually done not only in terms of absolute MAP but also in terms of what degradation is due to the errorful nature of the automatic speech transcription process. To this end, identical systems are evaluated using speech-recognized transcripts vs. perfectly transcribed documents, and the decrease in MAP is reported. Note that some evaluations speak of a 'relative' decrease in MAP, whereas others report absolute decrease in MAP, often leading to confusion in the reader.

Speech Recognition for SDR

The major challenge of automatic speech recognition for SDR is to transcribe real-world data that have not been recorded for SDR purposes. In such material, the audio may be of varying quality, from many speakers, recorded with unknown microphones under widely different environmental conditions, and cover a wide range of topical content. Each of these factors contributes to making the speech recognition problem very challenging.

A speech recognizer is applied to an audio stream and generates a time-marked transcription of the

speech. Time alignment allows pinpointing exactly where each word is spoken. Thus, all query terms or known relevant words can be marked on a timeline of the playback viewer. It is also possible to skip to the relevant portions of a longer document to facilitate efficient playback that skips irrelevant portions within a single audio document (Arons, 1994).

This transcript usually consists of words, but syllables and phonemes can also provide the basic transcription units. The transcript may be phone- or word-based in either a lattice (representing the confidence of each hypothesized word as well as its begin and end time), n-best list (multiple individual transcriptions), or, more typically, a 1-best transcript (the most probable transcription as determined by the recognizer).

Depending on the speech recognition technology and computer hardware used, the automatic speech recognition can take less than real time, such that a 1 hour long spoken document is transcribed in 60 min or less, or the speech recognition can involve multiple passes and take up to several hundred times real time, where many days are needed to process a single hour of speech with high accuracy. The redeeming factor is that this process only needs to occur once, at the time the archive of spoken documents is created.

The main speech recognition issues that affect the performance of SDR are related to (1) the vocabulary size of the automatic speech recognition system, (2) the word error rate of the automatic speech recognition system, and (3) removing nonspeech audio sections from the data.

Vocabulary Size in Automatic Speech Recognition for SDR

Automatic speech recognition systems tend to have fixed vocabularies of words that they can recognize. If the recognizer's vocabulary is small, many words will not be recognized, resulting in an inability to find these words later in the retrieval process. This is known as the out-of-vocabulary (OOV) problem. The OOV rate is the percentage of test set words that are not included in the recognizer's vocabulary and that therefore can never be correctly recognized. The problem is actually compounded by the fact that speech recognition systems tend not to know when they encounter an unknown word that is outside their vocabulary. Instead, they will fill in another word as a substitute, and to preserve continuity in the acoustic and language sequence, often an additional error is made afterwards. Studies have shown that each OOV results in almost one and a half word errors in the transcript (Rosenfeld, 1991). For speech recognizer vocabularies of less than 10 000 words, the OOV rate can be expected to be in the double digits, resulting in significant reductions in transcript accuracy and, consequently, lower retrieval effectiveness.

Although one would like the recognizer to distinguish between as many words as possible, each additional word in the vocabulary also results in additional potential confusions during recognition. As a practical matter, current recognizers are limited to a maximum of 64 000 words, which can be indexed in 16 bits or 2 bytes. A larger vocabulary quickly becomes prohibitively unwieldy, when one considers that a typical trigram language model allows $64\,000^3$ word sequences, even though not all combinations are likely to exist. A larger index, in addition to increasing the storage to 4 bytes per word, also implies a cubic increase in the space necessary for the language model. Fortunately, 64 000 words have been shown to be sufficient for many tasks due to Zipf's power law. In fact, there is only a minimal improvement in the OOV rate when recognizers increase their vocabulary from 51 000 to 64 000 words, where the OOV rate is approximately 1 or 2% (Woodland *et al.*, 2000). Clever selection of the right 64,000 word vocabulary, based on the expected thematic content of the audio, can further reduce the OOV problem (Garofolo *et al.*, 2000).

Even when the speech recognizer vocabulary is too small and actual query terms are not included in it, some of the degradation in the speech transcripts can be mitigated using phonetic search. In general, phonetic search is considered inferior to search on full words, but it can recover errors due to OOV words. The standard approach is to replace each word by an n-gram of phonemes (typically three or more phonemes). Thus, the name missing from the recognizer vocabulary such as 'Albright,' phonetically transcribed as 'ax l b r ay t,' would translate into a search for the phoneme trigrams 'ax l b,' "l b r,' 'b r ay,' and 'r ay t' as if they were words. Of course, an appropriate phone retrieval index would initially need to be constructed from the archived documents (Ng *et al.*, 2000).

Relationship of Word Error Rate to Retrieval Effectiveness

In general, WER is a good predictor of information. It also predicts how well named entities can be extracted (Kubala *et al.*, 1998) – that is, whether names, organizations, places, dates, and numbers can be correctly tagged as such in the speech transcript.

Although it is interesting to see how much information retrieval degrades with respect to a particular recognition word error rate, Figure 2 shows sample experimental data estimating spoken document retrieval effectiveness over a range of transcripts with

Figure 2 Degradation of retrieval effectiveness as a function of word error rate in a basic SDR system without query or document expansion. Data from Hauptmann and Wactlar (1997) with permission.

different error rates. The figure shows the relationship between information retrieval precision and speech recognition accuracy plotted as relative degradation to retrieval from manually transcribed text documents. The performance of a 'perfect' system is defined by the relevance judgments for documents and queries of a human judge of document relevance. This is equivalent to the WER of 0%. The quality of the information retrieval decreases as the speech recognition word error rate increases. For word error rates less than approximately 25%, the graph shows that retrieval performance degrades very little for transcripts with increasing word error rates and that retrieval is fairly robust to recognition errors. At speech error rates higher than 35%, the information retrieval effectiveness starts to decline noticeably. Similar results were obtained by Woodland *et al.* (2000).

Fortunately, the most accurate recognizers to date on the type of broadcast news data shown in Figure 2 produced a word error rate of approximately 20% for English broadcast news (Johnson *et al.*, 2001). One possible explanation is that the repetition and redundancy of key words in spoken language allow the relevant documents to be retrieved even when a substantial fraction of the words are incorrectly recognized. Once an essential set of correct key words are removed, however, the whole information retrieval paradigm quickly falls apart.

Other data show that modifying the speech recognizer to directly produce a transcript does not work because the speech recognition process depends strongly on the syntactic constraints provided by morphological variants and function words (Hauptmann *et al.*, 1998). There is evidence that allowing a speech recognizer to produce multiple alternate word candidates in the form of a confidence annotation lattice can reduce the effect of words missing from the single 'best guess' word candidate provided by the speech recognizer and thus improve information retrieval effectiveness (Siegler, 1999).

The consensus from a number of published experiments in this area is that as long as speech recognition has a word error rate less than 35%, information retrieval from the transcripts of spoken documents is only 2–10% worse than information retrieval on perfect text transcriptions of the same documents. Speech recognition within a reasonable error range is sufficient to perform information retrieval tasks with only a small decrease in information retrieval effectiveness (Garofolo *et al.*, 2000; Sparck-Jones *et al.*, 2001). Effective retrieval performance in SDR, especially from broadcast news, is thus a perfectly practical proposition.

Removing Nonspeech Audio Sections from the Data

A final contribution of speech recognition is to identify regions in the audio that do not contain speech. Nonlexical information derived directly from the audio, which would not normally be transcribed, can be used to improve SDR systems. Eliminating difficult to recognize sections of the audio track helps retrieval accuracy. Thus, when a system removes commercial advertisements, music, and poor quality audio regions, word transcription accuracy improves because there are fewer misrecognized words that

spuriously match query words during retrieval. Speech recognition approaches can aggregate acoustically similar passages; identify gender of the speaker; detect speech portions recorded by telephone; and identify silence, noise or music, repeated passages, and commercials. Audio repeats can accurately predict the presence of commercials, which can be filtered out before retrieval, and some broadcast structure information can be recovered by analyzing bandwidth, signal energy, and the presence of music. Segmentation of audio streams into coherent passages and browsing can also be improved by including automatically inserting markers for sentence boundaries and speaker turns. Removing music, commercials with speech, song and music, and other irrelevant material can further benefit the retrieval effectiveness for SDR (Johnson and Woodland, 2000). This automatically derived information also assists in the detection of 'document' boundaries in continuous audio streams.

Information Retrieval in SDR

This section provides an overview of the approaches used from the information retrieval side of SDR to improve retrieval efficiency and lessen the effects of incorrect speech transcriptions. The improvements on retrieval effectiveness concentrate on query expansion. If a collection of errorless text documents is available that is comparable to the audio archive, then document expansion and parallel corpus query expansion are also able to improve retrieval.

Query Expansion through Blind Relevance Feedback

It has long been known that longer queries result in higher precision retrieval. Blind (or pseudo-) relevance feedback, common for text retrieval, attempts to augment the query with terms from other relevant documents. For example, the system might take the top 10 documents returned after an initial retrieval cycle and pick the five most 'valuable' terms (according to a defined measure of term value) found in these documents. The assumption is that the top documents are likely to be highly relevant, and important terms in these documents not already in the query should help find other relevant documents. Since the retrieval is automatic, no user decides on the actual relevance of the selected documents or terms; hence, the selection is considered 'blind' or pseudo-relevance feedback. The top valuable terms are then added to the query before it is issued again against the archive. The effect is to make the query longer and richer in the words used to describe the query topic. The optimal number of terms and the optimal number of initial documents to use are dependent on the collection and subject to empirical determination.

Query Expansion through Blind Relevance Feedback from a Parallel Corpus

A variation on this theme is possible if a closely matched parallel corpus of similar documents is available. Similar to blind relevance feedback, the query is first issued to the parallel collection to retrieve highly relevant documents, from which valuable additional query terms are selected before the query is reissued against the spoken document archive. Of course, one can also combine both blind relevance feedback and parallel blind relevance feedback for query expansion.

Document Expansion through Blind Relevance Feedback from a Parallel Corpus

Another improvement in information retrieval for audio documents comes through document expansion, provided a parallel corpus is available. Instead of adding terms to the query, terms from the parallel collection are added to the actual audio document transcripts. This is accomplished by treating each audio document (or a passage from the audio document) as a query into the parallel collection. Again ('blindly') the most similar parallel documents retrieved are assumed to be relevant, and the most valuable terms are extracted from these documents and added to the original audio transcript.

Combined, as shown in Figure 3, these document and query expansion techniques can improve mean average precision by 17% or more. However, depending on the speech transcription error rate, the initial mean average precision, and the type of content, not all techniques work equally well all the time. For example, document expansion does not improve precision when the documents are already almost perfectly transcribed. In the most definitive studies, the degradation in mean average precision given a WER of 25% was reduced to approximately 2% compared to perfect transcription when all methods were combined.

SDR with Unsegmented Audio Data

Although one can think of many different ways to break a continuous audio stream into individual passages, stories, or documents, a simple approach of declaring a story boundary every 30 seconds has proved to be a remarkably good approximation, given that the WER and the lack of punctuation and formatting in speech recognition transcripts prevent many approaches based on linguistic features. To

Figure 3 Architecture of a full SDR system with parallel corpus document expansion, blind relevance feedback, and parallel blind relevance feedback.

avoid splitting a passage at some particularly critical junction, the story boundary windows are overlapped by 15 seconds. After retrieval, multiple overlapping windows are merged together for the final result list.

Compared to manually segmented audio documents, the retrieval effectiveness suffers an 8–10% absolute reduction in MAP, despite the use of various query and document expansion techniques described previously (Abberley *et al.*, 1999; Johnson *et al.*, 2001).

Research Trends in SDR

Evaluations of SDR showed that retrieval of audio documents can be extremely effective despite significant error rates in the speech transcripts. This insight resulted in SDR being considered a 'solved' problem, and research interest faded. Although some researchers have examined spoken queries, or heterogeneous collections of spoken, OCR, and text documents, there are two main directions of active research in SDR: cross-lingual SDR and video retrieval.

Cross-Lingual SDR

Cross-lingual SDR attempts to find audio documents spoken (and automatically transcribed) in one language using queries formulated in a different language. The problem becomes one of adequately translating the query with consideration of the of spoken document retrieval. In particular, bad translations and misrecognition of proper nouns can become very problematic so that a multiscale approach

seems promising, which combines word translation with syllable or phoneme translation and retrieval (Meng *et al.*, 2004).

Other variants of the cross-lingual SDR have attempted to use automatically transcribed documents in one language to find matching audio documents in a comparable, parallel collection in another language (Meng *et al.*, 2000). To date, combining SDR and machine translation into cross-lingual SDR still results in substantial degradation of retrieval effectiveness, which varies according to language pair and retrieval approaches used (Federico and Jones, 2003).

Video Retrieval

Video is a rich source of information, with aspects of content available both visually and acoustically. One prerequisite for achieving the goal of video retrieval is the automated information extraction and metadata creation from digitized video. The video retrieval research challenge is to automatically analyze both the visual and the audio component of video and make them retrievable by a user. Once the metadata have been extracted, queries can search the combined metadata of spoken language and visual documents. Since the video and image analysis does not have a well-defined vocabulary like speech recognition, a variety of 'semantic concepts' have been proposed to aid in automatically labeling the content of video shots. A successful approach for video retrieval requires the integration of speech retrieval, semantic concept analysis, and image retrieval (Kraaij *et al.*, 2004; Yan *et al.*, 2004).

Applications Using SDR

One of the fundamental lessons from SDR experiments is that currently achievable WERs in the speech recognition permit effective information retrieval. Using fairly standard information retrieval techniques, the current state of the art in speech recognition is adequate for information retrieval from audio archives. It is not too surprising that some interesting applications have transitioned from the research environments into full daily use.

There are a number of smaller companies that market meeting and lecture browsers that include speech recognition and SDR. The fundamental concept is to record audio and video of a presentation or meeting, analyze the audio, and allow retrieval, browsing, or summarization based on the extracted metadata. However, poor quality audio recording and high error rate transcriptions often make SDR difficult in these environments.

The HP SpeechBot is a successful attempt to index every audio file on the Web and make it available for search on a much larger scale (Thong *et al.*, 2002). It incorporates the basic SDR paradigm, extending it to cover a much richer variety of content and formats than has been studied in research labs. A recent addition to this is the NewsTuner, which is focused on broadcast audio streams available on the Web (Marston *et al.*, 2004).

One of the more ambitions SDR projects is associated with the Survivors of the SHOAH Visual History Foundation, which has videotaped interviews with 52,000 speakers in 32 different languages. These audio tracks are filled with verbal disfluencies, heavy accents by nonnative speakers, age-related pronunciation difficulties, and uncued speaker and language switching. A limited amount of metadata have been manually entered describing the speakers, the locations mentioned, and some content key words. A major effort is under way to convert these video interviews into a fully searchable SDR archive (Byrne *et al.*, 2004).

Spoken Language Production: Psycholinguistic Approach

K Bock, A Konopka and E Middleton, University of Illinois, Champaign, IL, USA

© 2006 Elsevier Ltd. All rights reserved.

Talking is action. Like most action, it is shaped by motives of many kinds. The study of language production in contemporary psycholinguistics centers on how different kinds of motives affect how people talk or, more broadly, how they convey information in language. In theory, the motives range across intentions to convey particular pieces of information, desires to impress listeners with one's erudition or eloquence, aims to articulate clearly and fluently, and everything in between. All these facets of communication are relevant to understanding language production. In current practice, most research focuses on how speakers accomplish the most rudimentary of their goals: producing utterances in English – or Dutch, French, Polish, or whatever the language of custom may be.

Simple and straightforward though this may seem, it is far from easy to explain how speakers accomplish this action. Producing an effective utterance

(one that says what the speaker means) in any language demands recruiting and deploying the linguistic resources appropriate for communicating one's thoughts. At the outset, this calls for being able to think in ways that are readily converted into language, or "thinking for speaking" (Slobin, 1996). Secondarily, it means bringing to mind words or morphemes that are suitable for conveying the thought, arranging the words or morphemes in the way the language requires so as to mean to the listener what the speaker means to say, and energizing the arrangements into sound forms through the actions of the speech musculature.

Just in case this process sounds easy, consider it in the following terms. A speaker of English who is about to describe where she lives must think about her residence in terms of some coordinate system that is, minimally, expressible in English and, desirably, comprehensible to an English-speaking listener. A precise way to do this is in terms of latitude and longitude: the house is located at 45.000688° north and 85.375743° west. However, someone who thinks to speak in these terms is unlikely to succeed in communicating information that is useful to a typical listener. A better tactic is to take account of where and why the conversation is taking place and what the listener knows and cares about, to consider what is called 'common ground' (Clark, 1996) in language, experience, and conversational aims. An important component of this form of perspective-taking is the speaker's retrieval of information about the listener from memory (Horton and Gerrig, 2002).

Having sketched some thought with the intention of communicating it, the speaker has the beginnings of what we term a 'message.' To transform the message into language and then into actual speech means retrieving from memory a tiny subset of the more than 45 000 words that an English-speaking high-school graduate knows, arranging them into one or more of the roughly 10^{30} relatively short English sentences, forming the necessary syllables from the 14 000 or so syllables that English includes, and articulating the syllables at a rate of roughly five per second, using more muscle fibers than any other mechanical performance of the human body (Fink, 1986). Speaking could be an Olympic sport were it not so universally mastered.

Because speaking *is* so universally mastered, one tends to take it for granted. To better appreciate this not-so-simple ability for what it is, in this article we examine some of the old and new discoveries of psycholinguistics that illuminate what goes on behind the scenes during mundane speech events. The discoveries rest on observations of spontaneous speech in natural settings, as well as on controlled experimental tests of language production in laboratory settings. In this brief survey, we limit ourselves to the psycholinguistic demands of creating messages, finding words, creating structures, and assembling phrases. For each of these topics, we focus on a few phenomena that disclose hidden challenges that speakers confront in the course of speaking and briefly review what is known about how the challenges are normally surmounted. Our survey neglects some fundamental facets of speaking, including most of the pragmatic and phonological processes that, respectively, start and end individual speech events. For excellent reviews of these topics, see Clark (1996), Dell and Sullivan (2004), and Levelt, Roelofs, and Meyer (1999).

Message-Making

How humans come to have communicative intentions (or intentions of any kind) is an epistemological mystery shrouded in philosophical controversy. How fluent speakers create from their communicative intentions a set of communicable meanings is closer to becoming a scientific problem that is amenable to careful observation and controlled investigation. One way in which the problem is tackled is by comparing the ways in which speakers of different languages go about forming messages. Consider a far-reaching difference between English and Chinese: in order to appropriately use singular and plural nouns and pronouns and the verbs that agree with them, English speakers must engage in rudimentary number cognition in virtually every utterance they produce. In contrast, Chinese speakers can ignore such distinctions because nothing in their language requires them. Are English speakers generally more attentive or sensitive to number differences than Chinese speakers and therefore more likely to include the information in their messages, simply *because* of this language difference?

The intuitive sense in such questions motivates the perennial appeal of an idea made famous by Sapir (1921) and Whorf (1956). According to the 'linguistic relativity' hypothesis, speakers of different languages experience their shared world in different ways, with the differences filtered through the lexical and grammatical devices of language. Slobin's (1996) thinking-for-speaking hypothesis is a more conservative variant of linguistic relativity that is specific to the question of making messages. Thinking-for-speaking implies that speakers must learn to conceptualize the kinds of distinctions that matter in the languages they speak, because the requirements differ among languages. In short, English speakers may have to think-to-speak number in ways that are

unnecessary, and maybe even impossible, for speakers of languages that treat number differently or do not treat it at all (cf. Gordon, 2004).

Unfortunately, the attractions of the linguistic relativity hypothesis are more than matched by the challenges of satisfactorily defining and testing it. Lucy (1992) provided a sympathetic analysis of the definitional problem; Pullum (1989) dispelled the many myths surrounding one familiar Whorfian claim – that Eskimos experience snow differently because their languages seem to have many words for snow. Tests of the hypothesis suffer from pitfalls – inherent in the disparate cultures and environments of people from disparate linguistic backgrounds (for example, the residents of Amazonian jungles differ from the residents of American suburbs in ways that go beyond language), in eliminating the contaminating effects of language from administration and performance of the experimental tests (important because the hypothesis has to do with an enduring impact of language on *nonlinguistic* cognition), and in the ease of interpreting any differences obtained in terms of linguistic relativity. However, there are provocative results consistent with the relativity hypothesis (Roberson *et al.,* 2000; Boroditsky, 2001; Bowerman and Levinson, 2001; Gordon, 2004), as well as continuing controversy (Levinson *et al.*, 2002; Li and Gleitman, 2002).

The properties of messages, as opposed to their contents, have begun to be illuminated in research on referential communication. One such property, a definitional property, is that messages are pre-verbal: they lack most of the trappings of language. The recollections of a victim of transient aphasia offer striking testimony to the absence of words in messages. His experience "was one of being fully aware of the target *idea* yet totally unable to accomplish what normally feels like the single act of finding-and-saying-the-word .... The idea ... was as complete and full as any idea one might have normally, but was not an unspoken mental sentence" (Ashcraft, 1993: 49).

One consequence of the pre-verbal nature of messages is that speakers cannot tell in advance when a message will give rise to linguistic ambiguity, and so speakers do not reliably disambiguate utterances that are made ambiguous by properties of the language. When a scene contains both a baseball bat and a flying (mammal) bat, speakers referring to just one of the objects are likely to call it a *bat*, failing to realize that from a listener's perspective, there are two *bats* (Ferreira *et al.*, in press). This does not seem to be due to sheer egocentricity on the part of speakers, because they do try to avoid ambiguity when it has a perceptual or conceptual basis. People describing scenes that contain the kinds of perceptual or conceptual similarities that make for referential ambiguities (e.g., a large and a small baseball bat) reliably refer to them with discriminating adjectives (e.g., *large* or *small;* Ferreira *et al.*, in press).

To frame messages in ways that are comprehensible to listeners, speakers may have to draw on fairly explicit experience about the kinds of information that listeners need. One supposes that frequent callers to an office in which two men are named Dave typically add the surname; if there is only one Dave or if the caller is unaware of the multiple Daves, the surname may be omitted more often. However, in many circumstances, speakers have to work hard enough merely to transform messages into language that they do not engage in the perspective-taking required to reckon with what listeners do and do not know (Brown and Dell, 1987; Keysar *et al.,* 2003). This transformation into language comprises the coordinated processes of finding words, assembling syntactic structures, and fitting words and structures together.

Finding Words

Words serve to invoke concepts. They do this by using largely arbitrary phonological emblems: the English *rabbit* is *konijn* in Dutch, *lapin* in French, and *królik* in Polish. To bridge the divide between meaning and sound in production, many theories postulate that there is an intermediate retrieval step in the transition from a concept to the sound form that conventionally conveys the relevant meaning. Because messages are not represented linguistically, appropriate words must be located within or retrieved from the vast mental dictionary in a speaker's memory. Word-finding occurs as part of a process of grammatical encoding, during which messages are transformed into abstract linguistic codes. The abstract codes for words are called 'lemmas' (Kempen and Huijbers, 1983; Levelt *et al.,* 1999) or 'lexical entries,' foyers of the mental lexicon (Bock, 1995).

Lexical entries may be located on the basis of meaning, of syntactic category information (e.g., noun, verb), and of the morphological or phonological forms with which they are associated. Entries are therefore accessible from messages, from the structural procedures that play out words into connected speech, and from sound (during comprehension or from recurrence within the production system). These multiple avenues make the lexical entryway a busy intersection in the process of production, as well as in comprehension (Levelt *et al.,* 1999), and the target of research aimed at uncovering how the intersection works. Two issues have received considerable attention: (1) the relative separability of the semantic,

grammatical, and phonological properties of words and (2) facilitation of retrieval by context, codability, and word frequency.

Regarding the separability of semantic, grammatical, and phonological properties, two familiar phenomena from the experience of normal speakers have been turned into tools for exploring how and how well different types of information are linked in the mental lexicon. One phenomenon is the tip-of-the-tongue (TOT) state, in which a known word eludes retrieval. TOT states offer abundant evidence for some separation of what a word means from how it sounds, because speakers can be fully aware of the meaning for which they are seeking a word without being able to come up with the word's form (Burke *et al.,* 1991). Speakers in this state may also report correct word-specific grammatical information, such as syntactic class or grammatical gender information (e.g., Vigliocco *et al.,* 1997). Anomic patients show the same dissociation between retrieval of grammatical information and sound information (Badecker *et al.,* 1995). This means that a speaker of Italian (for example) may know that a sought-for word is grammatically feminine without knowing anything about how the word sounds.

Error in speech is a second familiar phenomenon that also points to a separation of meaning and sound in lexical retrieval. The majority of speech errors tend to involve either whole words (which are retrieved on the basis of meanings in messages) or individual sounds (which are retrieved from lexical entries; Dell, 1995). The implication of this distribution of errors is that production involves processes that manipulate words and processes that manipulate phonemes. Whole-word errors can also reflect these two kinds of processes. Word-substitution errors sometimes show the influence of similarities of meaning (e.g., saying 'tomorrow' instead of 'yesterday') and sometimes of form (e.g., saying 'conversation' instead of 'compensation'). Errors of these and other types have served as the basis for influential theories of word and sentence production in both normal (Fromkin, 1971; Garrett, 1975; Dell, 1986; Garrett, 1988) and aphasic speakers (Garrett, 1992; Dell *et al.,* 1997; Foygel and Dell, 2000).

Another influential approach to word production emphasizes a different kind of evidence for the separation of meaning and sound, evidence about the speed with which the meanings and sounds of words are recovered during the naming of pictured objects (Levelt *et al.,* 1991). A strong intepretation of these data is that the retrieval of semantic and grammatical information strictly precedes the retrieval of phonological information (Levelt *et al.*, 1999). On this point, however, there is controversy. Although models of word production generally agree on a representational separation between lexical entries and phonological form in the mental lexicon (but see Caramazza, 1997), there is mounting evidence that, in the course of production, the temporal separation is not absolute. As candidate words for expressing messages are located, it seems that their corresponding word forms become active even before the speaker settles on which candidate to select.

So although semantic effects tend to be obtained early and phonological effects late during object naming (Schriefers *et al.,* 1990), the impact of phonological information can be observed before the semantically driven processes that settle on what word to use have run their course (Peterson and Savoy, 1998; Cutting and Ferreira, 1999). The concurrent activity of meaning and sound during word production can also be called on to explain errors that combine both semantic and phonological features of intended words (e.g., saying *rat* when *cat* was intended) and the tendency for sound errors to create real words at rates above chance (Dell and Reich, 1981; Dell, 1986; Martin *et al.,* 1989). The concurrent activity of meaning and sound constitutes a challenge to theories that posit discrete stages in word production.

The semantic and phonological properties of words are linked respectively to two powerful forces in word finding: conceptual accessibility and word-form frequency. The meanings of words vary in how specific they are, with some having a rich, coherent set of properties and others a weak and fairly sparse set. Because retrievability depends in part on the goodness of the match between the retrieval context (e.g., the circumstances in which a to-be-named referent presents itself) and the information associated with a word's meaning in memory, contexts with many relevant cues can facilitate naming in comparison to contexts with fewer cues (Griffin and Bock, 1998). Complementarily, words with sparser semantic representations (e.g., proper names and abstract words), are harder to retrieve than words with richer representations (e.g., concrete words), other things being equal (Burke *et al.,* 1991).

The familiarity of words, whether due to the frequency with which they are produced or the age at which they were learned, has long been known to affect how quickly or easily they are uttered. Higher-frequency words are produced faster than lower-frequency word forms (Oldfield and Wingfield, 1965), with an estimated decrease in production latency of roughly 30 msec for each $\log_{10}$ unit of frequency per million words in print (Glaser, 1992). The phenomenon of 'frequency inheritance' suggests that frequency affects the retrieval of word

forms more than access to lexical entries proper. Frequency inheritance refers to a finding that the production of low-frequency words (e.g., *wee*) benefits from the presence in the lexicon of high-frequency homophones (e.g., *we*; Dell, 1990; Jescheniak and Levelt, 1994) that are unrelated in meaning.

Creating Structures

There is more to sentence production than finding individual words. Even the speech that adults address to 9-month-old infants consists predominantly of multiword utterances. Setting aside vocatives and interjections, over 90% of what adults say to babies consists of more than one word (van de Weijer, 1999). The word groups that we produce combine in ways that are much more than the sums of their word parts, thanks to the workings of syntax.

The building of sentence structure is one of the most crucial but least understood facets of language production. This ability is crucial because, without a facility for assembling novel arrangements of words on the fly, speakers would be unable to adapt old thoughts to expression in new settings or to convey new ideas to anyone. Try to imagine freedom of thought with inflexible speech, leaving humans without the linguistic means to express new messages. The topic of structural formulation is also controversial thanks to its natural links to ongoing debates over the linguistic nature of syntax (Harris, 1993) and to the long-standing discomfort of some psychologists with structural abstractions (Bock, 1990). It is undeniable that connected speech is more than a limning of meaning, more than a string of words, and considerably more than "motor habits in the larynx" (Watson, 1913).

Vivid testimony to the structural underpinnings of everyday utterances again comes from the occurrence of speech errors. Intending to say "I got into a discussion with this guy" and instead saying "I got into this guy with a discussion" (Garrett, 1980) illustrates several truisms about the structural scaffolding behind words. First, something more than meaning guides word placement, because the typical products of errors are nonsensical, yet grammatical. Second, there are patterns in errors that disclose the mechanisms of word arrangement. Considering words in terms of their structural form classes rather than their meanings makes it evident that form class (e.g., noun, preposition, adjective) matters a great deal to structural assembly: words that are confused in errors are very likely to represent the same form class, as though the assembly process at some point selects words in terms of their structural rather than their semantic suitability.

Structural features of utterances also come to the fore in explaining the intricacies of that most scorned of topics in English grammar, subject-verb number agreement. Despite its effete overtones, agreement is in fact not only something that speakers do routinely (more than once every few seconds in running speech) but also something they do with surprising accuracy (even 4-year-olds get it right 94% of the time; Keeney and Wolfe, 1972). Consider what is involved in producing subject-verb agreement. First, speakers must understand what constitutes a subject. It is not just the first word or phrase in a sentence, because questions (cf. 'What *is* your name?' and 'What *are* your names?') and subordinate clauses of various kinds put subjects in other positions. Subjects are not associated with specific meanings reliably enough to predict the properties of normal agreement, and even those meanings that are most typical of subjects are no more reliable agreement controllers than atypical meanings (Bock and Miller, 1991). Even nonsensical sentences demand normal agreement: colorless green ideas *sleep*, not *sleeps*, furiously. What is crucial is not meaning, but the structural relationship to the rest of the sentence in which a subject appears. Second, speakers must determine what the verb is and which part of the verb carries number. Finally, there is the problem of determining what the number of the verb should be. There are competing theories about how this is determined (Eberhard *et al.,* in press, provide a review), but a traditional idea is that the number of the subject controls the number of the verb.

How do speakers decide on the number of the subject? Typically, the main considerations are the numerosity of the referent of the subject noun phrase (one or more than one thing), the lexical-grammatical number of the subject noun (singular or plural), and the presence in an utterance of plural nouns that are not the subject. The roles of referent numerosity and grammatical number are fairly obvious: when a referent comprises more than one thing, English speakers are likely to select plural nouns, and plural head nouns make for plural subjects. Nonetheless, the comparative contributions to agreement of the referential underpinnings and lexical contents of agreement controllers fuel a continuing debate (Middleton, Bock and Verkuilen, 2005).

The presence of nonsubject plural nouns in an utterance creates a tendency toward a type of error in agreement called 'attraction.' Attraction is illustrated in the statement, *The time for fun and games are over.* Like other kinds of errors, attraction discloses some of the mechanisms behind normal, error-free language production. Among its most salient properties

are two that point to the structural underpinnings of agreement. First, attraction does not occur willy-nilly, but respects basic structural boundaries: verbs are more attracted to nouns in their immediate structural vicinity than in their immediate temporal vicinity (that is, in the word string). For instance, they are more attracted to nouns within their own clauses than to nouns in other clauses, even when both nouns immediately precede the verb (Bock and Cutting, 1992).

Second, attracted verbs do not simply take whatever number is seemingly dictated by a neighboring noun; by and large, plurals are more likely to create attraction than singulars. Among other implications, this means that attraction is not the mistaken implementation of agreement with something that is not the subject; if it were, errors like *The king of the islands were cruel* (plural attraction) and *The kings of the island was cruel* (singular attraction) should be about equally likely. Because only plural attraction occurs reliably, despite the fact that plural verbs are in other respects less likely to err than singulars (Stemberger, 1985), it seems that what goes wrong is not agreement with the wrong subject, but rather agreement with the right subject that has somehow acquired the wrong number.

Another phenomenon that discloses the properties of the phrase-structure building in which speakers must engage is 'structural priming' (Bock, 1986). Speakers display a small but consistent tendency to echo the structures of utterances they have recently heard or recently said themselves. They do so even when the words and meanings conveyed by the echoed structure change between the first and subsequent occasions of use. These echoes are easy to find in spontaneous speech, as in this interchange from the Switchboard corpus about hanging wallpaper:

> Speaker B: "Repeating patterns <u>is what you have to check for</u> when you buy your paper."
> Speaker A: "Yes."
> •
> A: "That <u>'s what I needed</u> and I didn't think about that. I got a Mickey Mouse print <u>is what I got.</u>"

In this exchange, the same structure displayed in the underlined words of Speaker B ("is what you have to check for") shows up later, twice, in Speaker A's speech, the second time in a comparatively awkward locution ("I got a Mickey Mouse print *is what I got*"). Establishing that the structures behind the words can drive this repetition, experimental work has shown that structural repetition occurs in the absence of lexical repetition (Pickering and Branigan, 1998; Bock, 1989), in the absence of event role similarity (Bock and Loebell, 1990), and even across languages (Loebell and Bock, 2003). It persists across time (Saffran and Martin, 1997; Boyland and Anderson, 1998; Corley and Scheepers, 2002) and over interruptions by other structures (Bock and Griffin, 2000) in both adults and children (Huttenlocher *et al.,* 2002, 2004). Although structural priming is initially enhanced when words are repeated (Pickering and Branigan, 1998; Cleland and Pickering, 2003), the enhancement fades fairly rapidly, leaving a persistent structural effect of the same magnitude that occurs in the absence of lexical repetition (Konopka and Bock, 2005). This suggests separable sources for the lexical and structural effects observed in studies of structural priming.

There are two competing theoretical accounts of structural priming. One (Pickering and Branigan, 1998) rests on activation in so-called combinatorial nodes that are claimed to be responsible for sentence structure. Because combinatorial nodes are linked to words with corresponding syntactic privileges, this approach readily explains the lexical enhancement of structural priming. The second kind of account emphasizes the abstract structure building behind priming and its persistence. An explicit model of the process treats priming as a kind of implicit learning with natural links to language acquisition in children (Chang *et al.*, 2004).

Structure building and lexical selection are heavily dependent on one another. The fact that speakers are more likely to echo a recently heard structure when what they say also repeats a word from a priming structure is one consequence of this dependence (Pickering and Branigan, 1998; Cleland and Pickering, 2003), and it can be interpreted in terms of the bindings that must occur between words and structures at the outset of sentence formulation. A second consequence is related to the fact that some words are easier to retrieve than others: they are more accessible. Accessible information, including accessible words and accessible expressions (Bock, 1982), tends to be produced before less accessible information, provided that there is a structure into which it fits (Bock *et al.,* 2004). That brings us to the topic of incrementality.

Incrementality is a requirement of the processes of spoken language production, simply because the vocal output channel is heavily restricted in what it can do. Words and the syllables that compose them are uttered one at a time: even when two words erroneously blend together in speech (e.g., *slickery, flustrated*), they blend as a single word. The questions this poses for theories of production are (1) how incremental are the psycholinguistic preparation processes

in the run up to speaking, (2) what are the units of incrementation, (3) and what is the target of incrementation. To complicate matters, each of these questions must be addressed for each type of psycholinguistic formulation that goes on in production: included are at least the formulations of messages, words, syntactic structure, phonology (including prosody), and articulation.

Incrementation can be both hierarchical (Yngve, 1960; Kempen and Hoenkamp, 1987) and linear. The distinction between these two types of incrementation was drawn in terms of the timing of eye movements by Bock, Irwin, Davidson, and Levelt (2003). When speakers describe events in single sentences, their eye fixations on specific elements of the events tend to systematically precede the mention of those events during fluent speech (Meyer *et al.*, 1998; Griffin and Bock, 2000). This finding suggests that, at some level, planning may proceed roughly in terms of words or phrases in the order in which they occur. However, the existence of an underlying hierarchical component to planning is suggested by increased gaze durations, longer fixation latencies, and longer latencies to speech at the onset of utterances. This implies that in preparing an utterance, the scope of a plan extends beyond the upcoming word. Similar claims have been made on the basis of patterns of pausing, disfluency, and word repetition during spontaneous speech (Boomer, 1965; Clark and Wasow, 1998).

Conclusion

Until relatively recently, the normal processes of adult language production garnered little systematic attention from either linguists or psycholinguists. The reasons are well known and often recited. How people talk is hard to study (Bock, 1996) and easy to dismiss as a viable scientific problem (Fodor, 1983; Chomsky, 1986). Both of these issues have receded. There are now valid, reliable methods for getting at the underpinnings of production, burgeoning scientific interest in the language production ability, and fertile controversy over its nature.

We conclude with three questions about language production that remain far from a solution. From a linguistic standpoint, one puzzle about language production is how it relates to language comprehension. Linguistic communication works as well as it does because speakers and listeners know the same language, sharing a grammar and lexicon to encrypt and decrypt their ideas with a satisfactory degree of validity. Yet, do the grammar and lexicon function in the same ways during production and comprehension? Assuming a performance grammar, one that participates directly in processing and producing language (Kempen, 1999), at issue is whether any coherent grammar could function in the same ways during understanding and speaking, relying on the same basic mechanisms.

From a psycholinguistic standpoint, the key question about language production is how speakers put their knowledge of language to use *along with* their perceptual, attentional, conceptual, and motor abilities to adequately convey particular meanings at particular places and times to particular audiences. Knowing a language, having a grammar, is just one piece of this intricate puzzle. The grammar must be dynamic and configured in a way that fluently interfaces with a speaker's perceptions (auditory, visual, kinesthetic), thoughts, and other actions (prominently including gesture; McNeill, 1992) to support efficient communication.

The problem of integrating language with other cognitive and motor abilities is at the core of debates about the modularity of language and language processes (Fodor, 1983), a debate that is as relevant to the phenomena of language production as to language acquisition and comprehension (Bock and Kroch, 1989). If language abilities are no different in kind from other mental functions and skills, the question of integration, of interfacing language with other abilities, simply does not arise. What has to be explained, from this perspective, is how the stuff of general cognition can work to yield the human capacity to learn and use language.

If language is different in kind from other abilities – that is, a genetically distinctive human endowment – the explanatory challenge is greater. There is not only the issue of the interface between language and cognition. The nature and origins of the language capacity have to be explained and without the advantages of the animal models that have informed broad theories of human learning, cognition, and action. The development of neuroimaging techniques holds some promise for filling this gap (Indefrey and Levelt, 2000), although the study of production in particular still presents enormous challenges to current technologies. For these reasons, the controversy over modularity continues to be an organizing theme in the psycholinguistic study of language, bearing as it does on the basic questions of who we are as a species and why we talk.

'The media' were established as a distinct object of academic enquiry in the 1970s and only in the last 20 years has it emerged as a recognized field of research in its own right. The Media Studies agenda was, at first, largely political, and the language of news and the structure of the political interview have been widely studied. Sport, as written about in the daily press and as presented on radio and television, has only recently established itself as a subgenre (Whannel, 1992) in the study of the media. It has been largely concerned with the economics and politics of the globalization of sport via live television coverage of such key events as the Olympics for the whole world, the Superbowl for the Americans and the soccer World Cup for everyone else (Werner, 1998). Current interests in sport and the media are dominated by issues relating to the politics of identity (national/gendered/ethnic) in various fields of play and the festive experience of watching sporting occasions as media events (Dayan and Katz, 1992). Fitful attention has been paid to the style and presentation of sports coverage on television (Morse, 1983) but, with the exception of Stephanie Marriott's work discussed below, hardly any detailed linguistic work has thus far been produced.

The characteristic form of broadcast sports-talk is that of continuous commentary on a live-to-air sporting event of some kind. It might be wondered why broadcast events need commentaries. In the very first years of radio broadcasting, it was thought to be enough to place the microphones at strategic points to capture and relay the sounds of the event as it took place. This method was the one used, in 1926, for the first live transmission of the Derby, one of the biggest events in the British flat racing calendar. On the day, however, it rained solidly, the going was soft, and very little could be heard beyond the steady drip of the rain and faint cheering in the distance. Sporting events on radio have to be talked into being, and even television coverage needs a running commentary on behalf of viewers who are not present at the event itself.

How this commentary is done has been examined in Stephanie Marriott's detailed, careful study of the deictic features of television sports coverage. Linguistic deixis is sometimes defined in relation to speakers, but is more correctly understood in relation to the situation and circumstances of utterance. Any worldly situation consists of time, place, and persons; the irreducible components of any human occasion. Talk is unavoidably and always in a situation of some sort;

'The media' were established as a distinct object of academic enquiry in the 1970s and only in the last 20 years has it emerged as a recognized field of research in its own right. The Media Studies agenda was, at first, largely political, and the language of news and the structure of the political interview have been widely studied. Sport, as written about in the daily press and as presented on radio and television, has only recently established itself as a subgenre (Whannel, 1992) in the study of the media. It has been largely concerned with the economics and politics of the globalization of sport via live television coverage of such key events as the Olympics for the whole world, the Superbowl for the Americans and the soccer World Cup for everyone else (Werner, 1998). Current interests in sport and the media are dominated by issues relating to the politics of identity (national/gendered/ethnic) in various fields of play and the festive experience of watching sporting occasions as media events (Dayan and Katz, 1992). Fitful attention has been paid to the style and presentation of sports coverage on television (Morse, 1983) but, with the exception of Stephanie Marriott's work discussed below, hardly any detailed linguistic work has thus far been produced.

The characteristic form of broadcast sports-talk is that of continuous commentary on a live-to-air sporting event of some kind. It might be wondered why broadcast events need commentaries. In the very first years of radio broadcasting, it was thought to be enough to place the microphones at strategic points to capture and relay the sounds of the event as it took place. This method was the one used, in 1926, for the first live transmission of the Derby, one of the biggest events in the British flat racing calendar. On the day, however, it rained solidly, the going was soft, and very little could be heard beyond the steady drip of the rain and faint cheering in the distance. Sporting events on radio have to be talked into being, and even television coverage needs a running commentary on behalf of viewers who are not present at the event itself.

How this commentary is done has been examined in Stephanie Marriott's detailed, careful study of the deictic features of television sports coverage. Linguistic deixis is sometimes defined in relation to speakers, but is more correctly understood in relation to the situation and circumstances of utterance. Any worldly situation consists of time, place, and persons; the irreducible components of any human occasion. Talk is unavoidably and always in a situation of some sort;

deictic expressions of place (here and there), time (now and then) and persons (I, you, we) presuppose the common ground of the situation as given for all concerned. These components however are precisely what cannot be presumed in broadcast forms of talk. The work of maintaining the transparency of the nature of the situation is the task of the commentator, present at the event, on behalf of viewers who are not:

> A. Well that's the worst shot he's played throughout the break. Didn't really get high enough. He could try and split them but he's such a good potter I think it'll be a long blue into one of the corner pockets. Needs it to run a little. So **now** blue into the yellow pocket and if he gets this he will be pushing the pink towards the centre pocket. Well the blue's there.
>
> B. Great chance **now**.
>
> A. Yes and look for the roar if this pink and black goes in. (Mariott, 1995: 349, emphasis added.)

This live-to-air coverage of a world championship snooker match talks through what is visibly happening, from moment to moment, on screen for the viewing audience. Who 'he' (Steve Davies) is needs no gloss at this point, nor that 'the roar' will come from the live audience at the event if the pink and black go in. The meaning of 'pink' and 'black' and of 'long blue' and 'yellow pocket' though odd in transcription are all visibly self-evident at the moment of utterance. The 'long blue' describes the upcoming long shot facing Davies, who must pot the blue ball in the 'yellow' pocket (the pocket nearest the spot where the yellow ball is placed on the snooker table). The commentary, presuming viewers' minimal knowledge of the professional game of snooker, treats the personal and spatial components of the situation as transparently available to the television audience. But what particularly interests Marriott is the temporality of the occasion and its commentary. Live broadcasting reflexively reminds us that **all** talk exists in its **live** enunciatory moment of utterance. The now of the event is not the punctual now of digital time that exists in an eternal present that has no before or after, but a dynamic now in which the emergent present is in motion away from the past and towards the future.

Thus the two deictic 'nows' in the commentary indicate different moments in the unfolding, emerging present: the first 'now' is before the shot on blue, the second comes after it. But it is not a simple matter of before and after, first and second, time as succession. Each 'now,' though enunciated in its present moment, is oriented to the possible implications of what **has** just-now happened, **is** now happening, and **might** just happen next. The living present is the dynamic, moment-in-motion in which the temporalities of past-present-future encounter each other. In bounded, determinate live situations, that start, go on, and end (the basic temporal structure of all sporting events and of all conversations) there is always an intrinsic tension because, from moment to moment, the outcome is uncertain. Will Davies pot the blue? He does. And now the pink? Sports commentary is never, as Marriott shows, a mere description, but offers a continuing interpretation, evaluation, and account of what is seen to be going on. In so doing it is oriented to the experiential significance of the occasion for viewers, on whose behalf it offers its assessments. That significance is something that accumulates in and through the temporal dynamics of the event and its structured, from-start-to-finish now (for further discussion see Marriott, 1997). Live television, Marriott suggests, "lives off the instantaneousness and uncertainty of the moment very much the way we do in actual life."

Having established the temporal characteristics of the phenomenal now of the broadcast sporting occasion and its live-to-air commentary, Marriott went on to examine some of its surprising and unique features as they show up in instant replays:

> Here's a replay. **Now** you see Fittipaldi go out of the picture there and spinning – **Oh! And that's Gerhard Berger**. Well this this this is in effect a replay of Grand Prix that we have seen in these conditions before and I don't know what the answer is but it proves to me that it's a farcical situation (Marriott, 1996: 75).

In this replay from a Formula One car race, the commentator glosses the on-screen shot that replays the moment, a few seconds earlier, that Fittipaldi lost control of his machine. Even as he speaks, the commentator sees, on another monitor, Gerhard Berger spinning out of control on the track. There are thus two 'nows': the 'now' of the televised event (in which 'you [viewers] see Fittipaldi go out of the picture there') **and** the 'now' of the event itself (Gerhard Berger). Both are spoken of in the present tense, and yet the now of Fittipaldi to which television is attending is a moment just past while the now of Berger is the ongoing, live, and in-real-time moment of the race itself. Thus television creates a hitherto impossible, doubled now. Marriott points out that the replay is only of the visual recording (not its sound). What we **see** is the soundless past brought to visual presence. What we **hear** as we witness time regained on screen is the background ambient sound of the ongoing event in real time. But we barely notice this background because we are attending to the foreground commentary that is speaking to the moment just gone. Thus the past has entered into the present to create a now-and-then, a doubled temporality that is peculiar to and dependent on broadcasting's unique capacity

both to transmit live-to-air coverage of events in the world and, at the same time, record them. The doubled now of television is proved in this instance by the way in which the then of Fittipaldi collides with the now of Gerhard Berger, for it takes a moment or so before coverage can cut away from the replay of the first to the second now-and-in-present-time crash.

Marriott's work makes clear that the event-in-itself and the event-of-television are not the same. This disparity has sometimes given rise to anxieties that the latter is somehow a secondary, derivative experience compared with the authentic experience of being present at the event itself (Lang and Lang, 1982). However, Marriott establishes that both the event and the event-of-television are grounded in the same, immediate, shared, phenomenal now. It cannot be claimed that one is more 'live' than the other. Her scrupulous examination of the instant replay discloses the many-sided experiential character of the televised sporting event. Those who are present at the event see less of the action than the television viewer. They have only their own restricted point-of-view and that depends on where they are. The multi-camera coverage of live events offers multiple points of view from a wide range of perspectives (including the aerial blimp shot on big occasions) and, in replays, an impossible doubled temporality in which the event is instantly relived and reexperienced. Today huge plasma screens in sports grounds make those moments available to the crowds at the event so that they too do not miss what television makes available for those who are not there.

There is a nice irony in the fact that the technologies that make replays possible also allow for, in another application, the analysis of talk, including sports talk and the use of instant replays. It had long been assumed that language-in-use could not be systematically examined, because actual talk is a fleeting, transitory thing that lives and dies in the moment of speaking. Moreover, it was generally assumed to be incoherent and clumsy, full of hesitations, mumbles and repetitions in comparison with the tidy, orderly appearance of words in sentences on pages. Both J. L. Austin and H. P. Grice attempted to establish ordinary language as a fit object of enquiry against the prevailing skepticism of Oxford philosophy in the 1950s that regarded it as unfit for conceptual analysis on account of its "ambiguity, misleadingness, vagueness and the incorporation of mistakes and absurd assumptions." Both regarded "ordinary language as a wonderfully subtle and well-conceived instrument which is fashioned not for idle display but for serious (and nonserious) **use** (Grice, 1989: 178–179, 384, emphasis added).

However, the actual study of ordinary language-in-use depended on recording technologies developed in the first place by broadcasters to complement live radio and television transmission. The tape-recorder does something astonishing. It captures the liveness of worldly events and talk as they unfold and preserves them for later transmission and editing in ways that were hitherto impossible. It took the good genius of Harvey Sacks to apply broadcast recording technologies to the empirical study of talk-in-action (Sacks, 1995). Conversation analysis demonstrates in the finest detail what Austin and Grice had both surmised; namely the ordered, orderly character, the communicative logic, of conversation. Marriott's work, drawing on linguistics, pragmatics, and conversation analysis, uses recording technologies to examine their practical application and use by the broadcasters themselves. The management of the live situation is attended to in all aspects of the coverage of sporting and other worldly events, including the live-to-air talk of their professional commentators. Further forthcoming work, building on Marriott, shows how the communicative logic of broadcast commentaries is also implicit in the visual narrative to which they speak (Scannell, 2006).

St Christopher (Kitts) and Nevis: Language Situation

Editorial Team

© 2006 Elsevier Ltd. All rights reserved.

The Federation of Saint Kitts and Nevis (formerly Federation of St Christopher and Nevis) is located in the northern part of the Leeward Islands in the eastern Caribbean. It comprises two islands in the Leeward Islands group. Both are of volcanic origin, with a lush vegetation. St Kitts is the larger one and more developed of the two.

Christopher Columbus landed on St Kitts in 1493 and named it after St Christopher. He also came to Nevis on his second voyage, calling it Nevis because its resemblance to snowcapped mountains. The first European settlers of these islands were English and appeared on St Kitts in 1623 and on Nevis in 1628. They were followed soon after by the French, which gave rise to an Anglo-French rivalry that lasted for a century. After 1782 the islands came under permanent British control, together with Anguilla, as a self-governing state in association with Great Britain. Anguilla seceded in 1980, and St Kitts and Nevis became independent in 1983.

The original inhabitants of the islands, Arawaks and Carib Indians, were wiped out in a massacre in 1626. From the 1630s onwards, the islands were populated by African people who were brought in as slave workers for the sugar and tobacco plantations. As a result, a rich culture combining elements from Africa, Europe, and native American culture has evolved. The islands now have a population of 38 836 (July 2004 estimate). The residents are predominantly of African origin (90%), as well as British, Portuguese, and Lebanese origin. The official language is English. The local creole language is Leeward Caribbean Creole English (or Kittitian Creole English). The adult literacy rate is 97%.

St Helena: Language Situation

Editorial Team

© 2006 Elsevier Ltd. All rights reserved.

An uninhabited island in the southern Atlantic ocean until its discovery by the Portuguese in 1502, St. Helena became British East Indian Company territory in 1673 and a British colony in 1834. The island was an major port of call on the Cape route to the Indian Ocean until the opening of the Suez Canal in 1869, when its importance declined. Another role of St. Helena was to host exiles and prisoners of war, the most famous being the French emperor Napoleon Bonaparte, who was exiled to St. Helena in 1815 and died there in 1821. In the first half of the 20th century, Ascension Island and Tristan da Cunha (including Nightingale, Inaccessible, and Gough Island) became part of St. Helena.

The population of St Helena is around 7400. While ethnically a mixed community, including people of African, Chinese, and European background, the sole language of St. Helena is English.

St Lucia: Language Situation

Editorial Team

© 2006 Elsevier Ltd. All rights reserved.

St Lucia is located roughly in the centre of the Lesser Antilles, between Martinique to the north and St. Vincent and the Grenadines to the south. St Lucia was originally settled by Arawak and Carib speakers. The first European contact was with the Spanish in the early 16th century. However, it was French speakers from Martinique who established European settlement in 1650. During the following 100 years, the island was contested by French and English colonizers and fell from one to the other more than ten times. Eventually, the British assumed control of St Lucia in 1815, but strong contacts with Martinique remained, and French continued to be used in many domains. After a period of self-government, St Lucia became independent in 1979.

St Lucia's population is estimated at 164 000 (July 2004 est.). The official language is English, and 80% of the population are considered literate in English. However, the long influence of French on the island resulted in the development of the French-based Creole language Patwa or Kwéyòl (Lesser Antillean Creole French), which is still spoken by 75% of the population. At the times of French domination, there probably existed a Creole continuum, ranging from Standard French to Patwa. However, since English has replaced French as the main colonial language of St Lucia, the situation is one of bilingualism, with many St Lucians using Patwa and English in different contexts.

Traditionally, Patwa has been associated with low social standing and has played no role in any formal context. However more recently, after independence, Patwa has come to be viewed more positively and is being used in more public contexts, as well as in primary and adult education, where dictionaries, grammars, and other teaching materials for Patwa have been developed. The contact with English leads to increasing use of English lexical resources for Patwa.

St Pierre and Miquelon: Language Situation

Editorial Team

© 2006 Elsevier Ltd. All rights reserved.

St Pierre and Miquelon is an archipelago situated in the North Atlantic Ocean, south of Newfoundland. It is composed of three principal islands: St Pierre, Miquelon, and Langlade, with four small islands around St Pierre (Le Grand Colombier, Pigeon's Island, Victor's Island, and Sailor's Island). It is the only French enclave in North America, which since 1985 has enjoyed the status of 'territory with special status (*collectivité territoriale à statut particulier*).'

Archaeological discoveries show that the islands were already used as a seasonal base as early as many thousands of years ago by many native peoples, like the Beothuk and the Paleo Eskimo. During the 16th century, the islands were used as a base for seasonal cod fishery by the French of La Rochelle, Granville, Saint-Malo, and the Basque country. The name *Miquelon* was given by Basque fishermen from Saint-Jean de Luz. The French also settled in Saint-Pierre in the 17th century and fought with British colonizers for territorial rights, which resulted in fluctuated ownership. The treaty of 1763 returned the islands back to France, but even after this the islands were attacked by the British, and the locals suffered deportation. It is now a territorial collectivity of France. In the 18th century, the islands provided refuge for Acadian deportees from Nova Scotia.

The population of the islands (6995, July 2004 estimate) is French (who usually have strong patriotic feelings). Many people are originally from the Basque, Breton, and Normandy regions of France. The official language is French. The literacy rate is 99%.

St Vincent and the Grenadines: Language Situation

Editorial Team

© 2006 Elsevier Ltd. All rights reserved.

St Vincent and the Grenadines are situated in the southeastern Caribbean. The Grenadines comprise some 32 islands (the main, populated islands of which are Bequia, Balliceau, Canouan, Mayreau, Mustique, Isle D'Quatre, Petit Saint Vincent, and Union Island) south of St Vincent, which is the largest in the archipelago.

About 100 years before the first Spanish explorers arrived, the island was settled by Carib Indians, who had been preceded by Arawak settlers. The Carib people resisted European colonists for some time. The first permanent non-Carib settlers were African slaves, who were shipwrecked from a Dutch ship in 1675 and were later absorbed into Carib society. Their descendants became known as Black Caribs, to distinguish them from the native Yellow Caribs. The first European settlement was established by the French in the early 1700s, but the British also fought for the territory.

The economy was based on plantations until 1812, when an eruption of La Soufrière volcano destroyed most of the coffee and cocoa plants. In 1834, the abolitionist movement won; more than 18 000 slaves became free, and the planters called in foreign workers. Hurricanes and another eruption in 1902 destroyed the last plantations.

In 1969 St Vincent became a self-governing state in association with the United Kingdom, and in 1979 St Vincent and the Grenadines acquired full independence.

The number of the islands' inhabitants is 117 193 (July 2004 estimate), a number that has fluctuated with eruptions of La Soufrière.

The official language is English. Local languages are Windward Caribbean Creole English, with a dialect, Vincentian Creole English, as well as a French-based creole (French Patwa or Patois). Education is not compulsory. For many years, schools used only English, but recent years have accepted the use of the local creole in education as well. The literacy rate is 96%.

Standard and Dialect Vocabulary

P Trudgill, University of Fribourg, Fribourg, Switzerland

© 2006 Elsevier Ltd. All rights reserved.

A dialect is a variety of language that differs grammatically, phonologically, and lexically from other varieties and which is associated with a particular geographical area and/or with a particular social class or status group.

Standardization is the process by which a particular dialect of a language acquires or is assigned functional importance greater than the other dialects and is subject to codification and stabilization. Through these processes it acquires a publicly recognized and fixed form, in which norms are laid down for 'correct' usage as far as grammar, vocabulary, and spelling are concerned (Trudgill, 2003). This can take place over time without involvement of official bodies, as happened with Standard English, or it can take place quite rapidly, as a result of conscious decisions by governmental or other official planning agencies. The results of codification are usually enshrined in dictionaries and grammar books. For English, we can say, further, that Standard English is the dialect of English that is normally used in writing, is spoken by educated native speakers, and is taught to nonnative speakers studying the language.

Strictly speaking, then, standard varieties such as Standard English are just as much dialects as any other dialect. However, the term 'dialect' is often used to refer only to nonstandard dialects, and the opposition between 'standard' and 'dialect' vocabulary in this article must be understood in this sense – standard versus nonstandard vocabulary.

Because of its sociolinguistic history, Standard English has native speakers, which is not necessarily true of standard varieties of all languages. It is also, everywhere in the native-English-speaking world, a social dialect; it is typically spoken natively by speakers toward the top of the social class or social status scale. All other dialects of English can be referred to collectively as nonstandard English and typically have native speakers from lower social class backgrounds.

Nonstandard dialects are typically regional as well as social – they are associated with a particular geographical region. Standard English, on the other hand, is typically nonregional. It is true that Standard English is a polycentric standard variety, with English, Scottish, American, Australian, and other standard varieties differing somewhat from one another, but *within* these different countries, Standard English shows very little geographical variation – although it does have some, as we shall see.

Social and Regional Restriction

By this definition, dialect, i.e., nonstandard vocabulary, consists of lexical items that are not found in the standard variety. For English, such words are not found in the speech of native speakers of Standard English and they are not found in the dictionaries of the language, unless specifically marked 'dialectal.'

It follows, then, that a sure indication that a vocabulary item is nonstandard is that it is both regionally *and* socially restricted. To employ an English example, the nonstandard dialect of Norwich, England, has a verb *to blar*, which means 'to cry, weep.' This is clearly an example of 'dialect vocabulary' in that this verb is not only regionally restricted – to the dialects of this part of England – but is also socially restricted. That is, the proportion of the population of Norwich who are native speakers of Standard English do not normally use this word (although most of them will probably be aware of what it means).

It is words of this regionally and socially restricted type that are typically studied by dialectologists and therefore found in dialect atlases and other publications devoted to dialect study. Trudgill (1999: 124), for instance, presented a map of dialect words for 'girl,' based on the research of the Survey of English dialects, which investigated conservative rural dialects in England in the 1950s and 1960s. The words are *maiden*, in the Southwest, *wench* in the West, *lass* in the North, and *mawther* in East Anglia. However, the dialect word in the South Midlands and South is *girl*. This is probably because, whereas Standard English is today a purely social dialect, its historical origins were in the southeast of England. Similarly, the word used for 'ear' by nonstandard dialect speakers is *lug* in the east and north of England, but *ear* in the south.

In some cases, regionally restricted words are words that were formerly found in all areas, but which have become regionally limited over time. For example, *fall* used to be a general word for 'autumn,' but is now confined to the dialects of the Southwest and Lincolnshire. (It is still also used, of course, in the Standard English of North America.) In other cases, regional variation in lexis may reflect different patterns of language contact. Contact with Old Norse is responsible for northern English dialect words such as *laik* 'play' and *lop* 'flea,' whereas a Dutch influence can be seen in East Anglian dialect words such as *dwile* 'dishcloth' and *push* 'pimple.' The Herefordshire dialect similarly has words of Welsh origin, such as *tallet* 'hayloft.'

Regional without Social Restriction

Dialect vocabulary, then, consists of words that are not used by speakers of the standard variety of the language and which are both regionally and socially restricted. On the other hand, it does not follow that words that are regionally but not socially restricted (in the sense of social class or status) can be referred to as 'dialect vocabulary.' For example, the word *ashet* 'large plate' is regionally restricted within the English-speaking world to Scotland and New Zealand, but in those areas it is used by all speakers, including Standard English speakers, and is therefore in no sense an item of 'dialect vocabulary.' Similarly, *faucet* 'tap' is confined to North American English, but is used there by Standard English speakers. And *plimsolls* 'gym shoes' is restricted to the south and east of England, but is used at all social levels. This is a consequence of the fact, referred to above, that Standard English is a polycentric variety and that it does admit small amounts of regional variation even within specific countries.

Social without Regional Restriction

Because Standard English is a social dialect, it would in principle follow that words that were socially but not regionally restricted would also constitute 'dialect vocabulary.' However, there are no such words. This results from the fact that there is no way in which words can be described as 'standard vocabulary.' It may seem paradoxical that 'dialect vocabulary,' i.e., 'nonstandard lexis' should be a legitimate term but that 'standard vocabulary' should not be, but this is a perfectly natural consequence of the nature of standardization. The vocabulary of Standard English is available to all speakers; we can be sure that dialect speakers in the southwest of England in the 1950s knew and used the word *girl* as well as the word *maiden*.

Similarly, to take the Norwich *blar/cry* example, it could be suggested that *to cry* is a Standard English word, whereas *to blar* is not. However, *cry* is by no means *only* a Standard English word, since there are very many other nonstandard dialects elsewhere in which it is the only word available with this meaning, and even in the working-class nonstandard dialect of Norwich, *to cry* is a perfectly common and frequently used word. Thus, if 'Standard English vocabulary' is supposed to mean 'vocabulary that occurs in the Standard English dialect and no other,' then there is no such thing.

Unlike *mawther,* the word *girl*, despite being the dialect word for 'girl' in the south of England, is not a dialect word as such because it also occurs in Standard English. But crucially for the argument here, it cannot be described as a 'standard' word either, because it is available to all English speakers, including nonstandard speakers, and indeed, as we have seen, in the south of England it is the *only* word available, even to nonstandard speakers.

Style and Register

A further issue concerns vocabulary that is formal and technical and therefore more likely to occur in the speech of educated people. Consider the sentence:

(1) Father was exceedingly fatigued subsequent to his extensive peregrination.

It could be suggested that words such as *fatigued* and *peregrination* are confined to the speech of those social classes who speak Standard English and are therefore 'standard vocabulary.' Further consideration, however, will reveal that what we are seeing here is not a dialect difference – standard versus nonstandard dialect – in vocabulary, but a stylistic difference. Styles (see Trudgill, 2003) are varieties of language viewed from the point of view of formality and which can occur on a continuum ranging from very formal to very informal. Formal styles are employed in social situations that are formal, and informal styles are employed in social situations that are informal. The differentiation then has no necessary connection with social class or status and thus no connection to social dialect.

This becomes clearer if we consider the following sentences in contrast to (1):

(2) Dad was very tired after his lengthy journey.

(3) The old man was bloody knackered after his long trip.

These three sentences have more or less the same referential meaning and differ only in style, with the stylistic differences being indicated by lexical choice: (1) is (ridiculously) formal; (2) is stylistically neutral; and (3) is informal. We cannot, however, say that *peregrination* is 'standard' and that *trip* and *journey* are not. All dialects incorporate different stylistic levels, and Standard English is no different from any other (nonstandard) variety of the language in this respect. Speakers of Standard English have a full range of styles open to them and can swear and use slang just like anybody else. Equally, nonstandard speakers are not single style speakers either. There is no necessary connection between dialect and style and therefore no way in which formal vocabulary

can be considered standard and informal vocabulary nonstandard. Sentence (3) is standard but informal, whereas the following sentence is neutral but nonstandard:

(4) Dad were very tired after his lengthy journey.

Similarly, it could be argued that specialized, technical vocabulary is inherently 'standard.' This is also not so. The sociolinguistic term *register* is generally employed to refer to a variety of language determined by topic, subject matter, or activity, such as the register of physics, the register of law, or the register of football. This is almost exclusively a matter of lexis. However, it would make no sense to identify vocabulary from certain more erudite registers as 'standard,' since the question of register and the question of standard versus nonstandard are in principle entirely separate questions. One can certainly acquire and use technical registers without using Standard English, just as one can employ nontechnical registers while speaking or writing Standard English. There is no necessary connection between the two. Thus,

(5) There was two eskers what we saw in them
U-shaped valleys

is a nonstandard English sentence couched in the technical register of physical geography (Trudgill, 1999).

This type of combination of technical register with a nonstandard variety is much more common in some language communities than others. In German-speaking Switzerland, for example, most speakers use their local nonstandard dialect in nearly all social situations and for nearly all purposes. Thus, it is that one may hear, in the corridors of the University of Fribourg, two theology professors discussing the works of Küng using all the appropriate theological vocabulary with the phonology and grammar of their local dialect.

Introduction

A 'standard' linguistic variety exists in almost all modern speech communities. Its prestige and legitimacy as 'standard' does not derive from any innate linguistic quality or historical precedence, or even from the fact that it is the most commonly spoken variety. It derives rather from an ideology forged and maintained by social institutions which valorize a particular variety over others and attempt to naturalize its ideological dominance. As Silverstein (1996: 285–286) defines it, "standardization . . . is a phenomenon in a linguistic community in which institutional maintenance of certain valued linguistic practices – in theory, fixed – acquires an explicitly-recognized hegemony over the definition of the community's norm." Researchers thus, ask how a particular variety came to be recognized as the standard, what social, political, and historical conditions made it possible, and what the consequences of standardization are. The study of language standardization, therefore, is less about language itself as function and structure, than it is about ideologies and hegemonies about language, or what is called 'language ideology' (Silverstein, 1979; Woolard and Schieffelin, 1994; Schieffelin *et al.*, 1998; Blommaert, 1999). Critically, linguistic anthropologists recognize that a particular valorization of the given language may actually influence its form, function, and structure, thus reversing the commonsense understanding within the ideology of the relationship between linguistic essence and social value.

The focus on the **process** of language standardization rather than on the standard language makes it immediately clear that the dominance of a particular linguistic variety is never stable or complete. While the imposition of technologies of linguistic uniformity upon the population universally characterizes the phenomenon of language standardization, this does not mean that people automatically accept and speak it. On the contrary, hegemonies are often met with counterhegemonies, and the legitimacy of the dominant language is often challenged and contested by some subgroups of the community that speak a variety

can be considered standard and informal vocabulary nonstandard. Sentence (3) is standard but informal, whereas the following sentence is neutral but nonstandard:

(4) Dad were very tired after his lengthy journey.

Similarly, it could be argued that specialized, technical vocabulary is inherently 'standard.' This is also not so. The sociolinguistic term *register* is generally employed to refer to a variety of language determined by topic, subject matter, or activity, such as the register of physics, the register of law, or the register of football. Introduction

A 'standard' linguistic variety exists in almost all modern speech communities. Its prestige and legitimacy as 'standard' does not derive from any innate linguistic quality or historical precedence, or even from the fact that it is the most commonly spoken variety. It derives rather from an ideology forged and maintained by social institutions which valorize a particular variety over others and attempt to naturalize its ideological dominance. As Silverstein (1996: 285–286) defines it, "standardization . . . is a phenomenon in a linguistic community in which institutional maintenance of certain valued linguistic practices – in theory, fixed – acquires an explicitly-recognized hegemony over the definition of the community's norm." Researchers thus, ask how a particular variety came to be recognized as the standard, what social, political, and historical conditions made it possible, and what the consequences of standardization are. The study of language standardization, therefore, is less about language itself as function and structure, than it is about ideologies and hegemonies about language, or what is called 'language ideology' (Silverstein, 1979; Woolard and Schieffelin, 1994; Schieffelin *et al.*, 1998; Blommaert, 1999). Critically, linguistic anthropologists recognize that a particular valorization of the given language may actually influence its form, function, and structure, thus reversing the commonsense understanding within the ideology of the relationship between linguistic essence and social value.

The focus on the **process** of language standardization rather than on the standard language makes it immediately clear that the dominance of a particular linguistic variety is never stable or complete. While the imposition of technologies of linguistic uniformity upon the population universally characterizes the phenomenon of language standardization, this does not mean that people automatically accept and speak it. On the contrary, hegemonies are often met with counterhegemonies, and the legitimacy of the dominant language is often challenged and contested by some subgroups of the community that speak a variety

different from the standard form, which may not even be available to them on 'equal' terms (think, for example, of the scarcity of access to Standard English in the stunning inequalities at the heart of U.S. public and higher education systems). People who speak nonstandard varieties often view the dominant language as a form of (symbolic) domination, and may consider their own linguistic variety as an emblem of solidarity and resistance. In this sense, language standardization is a complex process that includes its own 'failures,' and researchers pay careful attention to how people define themselves as members of groups with specific 'cultures' through language use. Issues of cultural and political identity are central to public debates around language standardization. Consider the examples of English-only policies, and the controversy of 'Ebonics' ('African American Vernacular English [AAVE]', a variety of English spoken by African Americans; Baugh, 2000). It is also the case that institutions, organizations, and agencies may recognize and take into account the failures of language standardization. For example, even when state authorities designate a particular language or variety as the national language, they often recognize that alternatives must be made available to the governed population, as in providing signage and reading materials in Spanish, Chinese, and Vietnamese, as well as in English, in many U.S. cities. The business world, of course, recognizes clearly that the 'standard' language may be woefully inadequate, and Spanish, Chinese and other varieties of the Yellow Pages are common in global cities. Such realities actually have the potential to undermine and eventually transform the symbolic value of the national language in particular localities, and that is, of course, precisely why we see the rise of defensive movements ('English only') at precisely those time and in those places where 'the standard' is in danger of losing its claim to privilege.

Standardization entails complex and dynamic power struggles among competing and divergent language ideologies, promoted by different groups and institutions. Ethnographic studies of language standardization thus pay close attention to the historical, political–economic, and cultural specificity and diversity of the ways in which a particular language came to be standardized and normalized, as well as to strategies, modes, and rationality of resistance and contestation to the hegemony of the standard.

Standardization, Modernization, and Nation-State Formation

The governmental idea of standardizing language is closely connected with the formation of the modern nation-state. In late 18th century western Europe, where the idea of the nation and nationalism was conceived in the strand of Romantic philosophy and philology, thinkers such as Johann Gottfried von Herder (1744–1803) argued that the repository of sovereignty is not the king or the state, but 'the people' or 'the nation,' rooted in a shared culture, tradition, history, and language. Indeed, language played a particularly important role in Herder's idea of the nation and the forging of national identity because he thought of language as the historically accumulated, spiritual essence of the primordial 'culture,' or the organic world view unique to a people. Accordingly, the relationship between standard language and nonstandard variations is conceived in the modern paradigm of the nation-state not as politics of differentiation (as the language standardization model discussed above would have it), but as a natural, phylogenetic branching in which the standard is understood as a historical and linguistic prototype or root from which the variations deviate but are still organically connected. Since the identification of one nation with one language served as a powerful moral ground on which to claim political sovereignty in nationalist movements, this model served nation-state formation not only in western Europe, but also by national subgroups with separatist agendas, as well as colonial and postcolonial populations.

If, as Benedict Anderson (1983) tells us, the nation-state idea is available for pirating, so is the idea of a standard language. In tandem with Herderian, primordial, nationalist rhetoric, language standardization has been one of the crucial projects of national modernity, seemingly obligatory in the context of industrial capitalist takeoff, urbanization, rational-bureaucratic state formation, and the emergence of civil society. In modernizing social institutions, such as education, labor markets, administration, the military, and the media, and in nationalizing the populace as the nation's citizen-subjects, language standardization was associated explicitly with the instrumentalist notions of 'efficiency,' 'progress,' and 'rationality.' The dream of a universal state language is rooted in the image of a well-ordered communication machine (thus our recognition of how an 'Orwellian' language will have its advocates). Governmental projects at all levels have included ideas regarding a standard language. Thus, whether the 'unity' of 'a people's' language is an effect of nationalist imaginings or modern governmentality, a standard language is never identifiable with naturally primordial or primary root language, but is always historically emergent and politically saturated.

Because a modern standard language originated in the core of capitalist modernization in western Europe, many non-Western countries intent on

modernizing have viewed creating a standard national language as essential and a sign of progress and development on a par with the West. In late 19th-century Japan, for example, a language modernization movement evolved out of a keen awareness on the part of the nation's elite of the absence of a standard Japanese, which they perceived as the sign of backwardness. In a contradictory, yet unified, rhetoric that claimed Japan's world status as a modern nation-state akin to those in the West, on one hand, and its particularity and autonomy from the West, on the other hand, modernizing the country was synonymous with modernizing its language (self-consciously asserted to be as unique – as **non**-Western – as Japanese 'civilization'), which meant creating a standard, national language (Inoue, 2002). Likewise, the creation of the Thai national language was part and parcel of the modernization of the Thai nation. A new language – newly **national** – was created by reforming tense and pronoun systems, coining new lexicons, and other changes, in reference to European languages such as English (Diller, 1988). In both the Japanese and Thai cases, language modernization meant approximating European languages, including having one single standard national language.

The Culture of Monoglot Standardization and Linguistic Markets
